## **Chapter 1. Canonical Decomposition**

- 1. Prime Decomposition.**
- 2. Torus Decomposition.**

## **Chapter 2. Special Classes of 3-Manifolds**

- 1. Seifert Manifolds.**
- 2. Torus Bundles and Semi-Bundles.**

## **Chapter 3. Homotopy Properties**

- 1. The Loop and Sphere Theorems.**

These notes, originally written in the 1980's, were intended as the beginning of a book on 3-manifolds, but unfortunately that project has not progressed very far since then. A few small revisions have been made, but much more remains to be done, both in improving the existing sections and in adding more topics. In particular an exposition of Haken manifolds was planned for §3.2. For any future updates which may be written, the reader should check my webpage:

<http://www.math.cornell.edu/~hatcher>

The three chapters here are to a certain extent independent of each other. The main exceptions are that the beginning of Chapter 1 is a prerequisite for almost everything else, while some of the later parts of Chapter 1 are used in Chapter 2.

# Chapter 1. Canonical Decomposition

The first section of this chapter is devoted to what was historically the first general result on 3-manifolds, Kneser's theorem that every compact orientable 3-manifold  $M$  decomposes uniquely as a connected sum  $M = P_1 \# \cdots \# P_n$  of 3-manifolds  $P_i$  which are prime in the sense that they can be decomposed as connected sums only in the trivial way  $P_i = P_i \# S^3$ .

After the prime decomposition, we turn in the second section to the canonical torus decomposition due to Jaco-Shalen and Johannson.

We will work in the  $C^\infty$  category throughout. Some basic results about differentiable manifolds will be needed. In particular this includes:

- Tubular neighborhoods: submanifolds have neighborhoods that are diffeomorphic to their normal bundles, and these neighborhoods are unique up to isotopy.
- Isotopy extension: an isotopy of a submanifold can be extended to an isotopy of the ambient manifold.
- Transversality: a submanifold of codimension  $p$  can be perturbed by a small isotopy to intersect another submanifold of codimension  $q$  transversely, and then the intersection is a submanifold of codimension  $p + q$ .
- Triangulability: a smooth manifold is homeomorphic to a simplicial complex whose simplices are smoothly embedded.

**Convention:** All manifolds in this chapter are assumed to be compact and connected, possibly with boundary, unless otherwise stated or constructed. Often we restrict attention to orientable 3-manifolds, although extensions to the nonorientable case are usually not too difficult.

## 1. Prime Decomposition

Implicit in the prime decomposition theorem is the fact that  $S^3$  is prime, otherwise one could only hope for a prime decomposition modulo invertible elements, as in algebra. The fact that  $S^3$  is prime is a consequence of Alexander's theorem, our first topic.

### Alexander's Theorem

This quite fundamental result was one of the earliest theorems in the subject:

|| **Theorem 1.1.** *Every embedded 2-sphere in  $\mathbb{R}^3$  bounds an embedded 3-ball.*

The version of this that Alexander proved, in the 1920s, was slightly different: a piecewise linearly embedded sphere in  $\mathbb{R}^3$  bounds a topological ball. It would not have been difficult for him to improve the conclusion to say that the ball was piecewise linear as well. The famous example of the Alexander horned sphere, which he constructed at about the same time, shows that a topological sphere need not bound a topological ball. The proof we give for smooth spheres follows the same general strategy as Alexander's proof for piecewise linear spheres, namely, to cut the given sphere along horizontal planes to produce simpler spheres and apply an induction argument. Alexander cut along horizontal planes passing through vertices of the triangulated sphere. In the smooth category one cuts instead along horizontal planes that are transverse to the sphere. In order to have a nice starting point for the induction we will do a preliminary isotopy of the sphere to arrange that the projection of the sphere onto the  $z$ -axis is a morse function, so we will assume the reader knows a little Morse theory. This could be avoided by using a more direct construction as at the beginning of [Hatcher 1983], but this would slow down the exposition.

The proof will also use the analogous result in one lower dimension, that a smooth circle in  $\mathbb{R}^2$  bounds a smooth disk. This can be proved by a similar but simpler inductive argument, and it would be a good exercise for the reader to work this out. In two dimensions it is even true that a topologically embedded circle in  $\mathbb{R}^2$  bounds a topological disk, the Schoenflies theorem, but the proof is more difficult since a simple inductive argument is not possible.

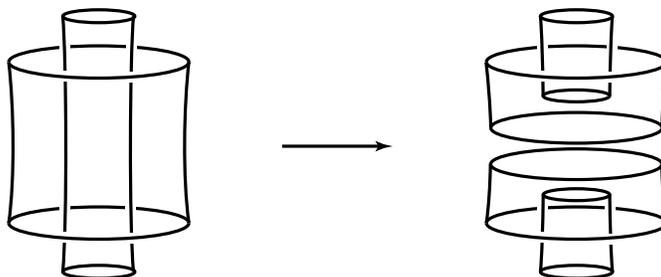

There is a simple proof due to M. Brown in 1960 that a smoothly embedded  $S^{n-1}$  in  $\mathbb{R}^n$  bounds a topological ball, for arbitrary  $n$ . The ball is known to be a smooth ball for all  $n$  except  $n = 4$  where this question remains open. For  $n \geq 5$  this follows from the h-cobordism theorem (plus surgery theory in the case  $n = 5$ ). Brown's theorem in fact has a weaker hypothesis than smoothness, just that the embedding is locally flat, so near each point of the embedded sphere there is a local coordinate system for  $\mathbb{R}^n$  in which the sphere becomes a linearly embedded  $\mathbb{R}^{n-1} \subset \mathbb{R}^n$ .

**Proof of Alexander's Theorem:** Let  $S \subset \mathbb{R}^3$  be an embedded closed surface, with  $h: S \rightarrow \mathbb{R}$  the height function given by the  $z$ -coordinate. The first step is to arrange that  $h$  is a morse function, as follows. We can approximate  $h$  arbitrarily closely by a morse function, and the linear path between  $h$  and the approximation gives a small homotopy of  $h$ . Keeping the same  $x$  and  $y$  coordinates for  $S$ , this gives a small homotopy of  $S$  in  $\mathbb{R}^3$ . Since embeddings are open in the space of all maps (with the  $C^\infty$  topology), if this homotopy is small enough, it will be an isotopy. By a further

small isotopy we can also assume the finitely many critical points of  $h$  (local maxima, minima, and saddles) all have distinct critical values.

Let  $a_1 < \cdots < a_n$  be noncritical values of  $h$  such that each interval  $(-\infty, a_1)$ ,  $(a_1, a_2)$ ,  $\cdots$ ,  $(a_n, \infty)$  contains just one critical value. For each  $i$ ,  $h^{-1}(a_i)$  consists of a finite number of disjoint circles in the level  $z = a_i$ . By the two-dimensional version of Alexander's theorem, each circle of  $h^{-1}(a_i)$  bounds a disk in the plane  $z = a_i$ . Let  $C$  be a circle of  $h^{-1}(a_i)$  which is innermost in the plane  $z = a_i$ , so the disk  $D$  it bounds in this plane is disjoint from all the other circles of  $h^{-1}(a_i)$ . We can use  $D$  to **surger**  $S$  along  $C$ . This means that for some small  $\varepsilon > 0$  we first remove from  $S$  the open annulus  $A$  consisting of points near  $C$  between the two planes  $z = a_i \pm \varepsilon$ , then we cap off the resulting pair of boundary circles of  $S - A$  by adding to  $S - A$  the disks in  $z = a_i \pm \varepsilon$  which these circles bound. The result of this surgery is thus a new embedded surface, with perhaps one more component than  $S$ , if  $C$  separated  $S$ .

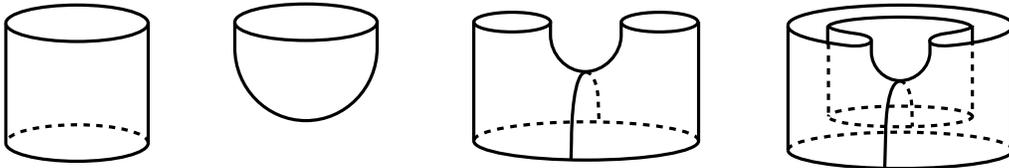

This surgery process can now be iterated, taking at each stage an innermost remaining circle of  $h^{-1}(a_i)$ , and choosing  $\varepsilon$  small enough so that the newly introduced horizontal cap disks intersect the previously constructed surface only in their boundaries.

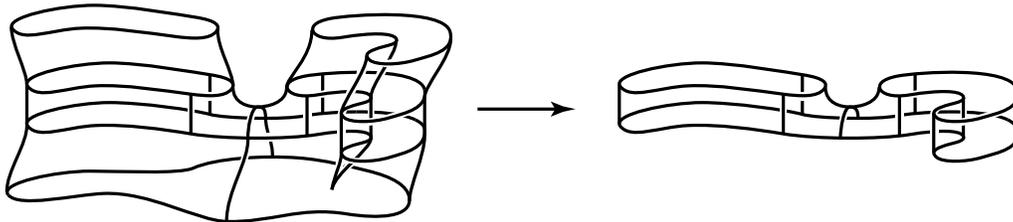

After surgering all the circles of  $h^{-1}(a_i)$  for all  $i$ , the original surface  $S$  becomes a disjoint union of closed surfaces  $S_j$ , each consisting of a number of horizontal caps together with a connected subsurface  $S'_j$  of  $S$  containing at most one critical point of  $h$ .

The surgery construction as we have described it produces surfaces in  $\mathbb{R}^3$  that are not smooth along the curves bounded by the horizontal caps since they have two distinct tangent planes at each point of these curves, one tangent plane being horizontal and the other one not horizontal. It would be easy to modify the definition of surgery to round these corners and make all the surgeries produce genuinely smooth surfaces. There will be many other occasions throughout the book where manifolds with corners arise, and we will let the smoothing of these corners be implicit.

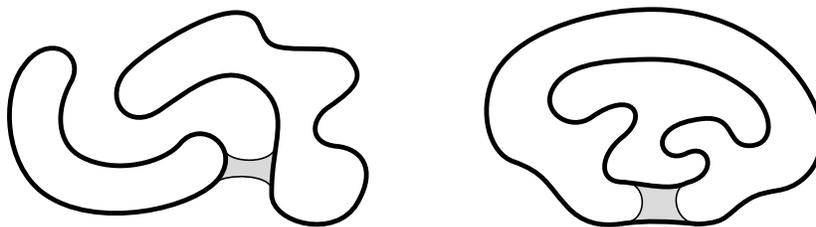

**Lemma 1.2.** *Each surface  $S_j \subset S$  is isotopic to one of seven models: the four shown below plus three more obtained by turning these upside down. Hence each  $S_j$  is a sphere bounding a ball in  $\mathbb{R}^3$ .*

**Proof:** Consider the case that  $S_j$  has a saddle, say in the level  $z = a$ . First isotope  $S_j$  in a neighborhood of this level so that for some  $\delta > 0$  the subsurface  $S_j^\delta$  of  $S_j$  lying between the planes  $z = a + \delta$  and  $z = a - \delta$  is vertical, with vertical tangent planes, except in a neighborhood of the saddle where  $S_j$  has the standard form of the saddles in the models. Next, isotope  $S_j$  so that its subsurface  $S_j'$ , the complement of the horizontal caps, lies in  $S_j^\delta$ . This is done by pushing its horizontal caps to lie near  $z = a$ , innermost caps first, keeping the caps horizontal throughout the deformation.

After this has been done,  $S_j$  is entirely vertical except for the standard saddle and the horizontal caps. Viewed from above,  $S_j$  minus its horizontal caps then looks like two smooth circles, possibly nested, joined by a 1-handle, a neighborhood of an arc joining the two circles.

Since these circles bound disks, they can be isotoped to the standard position of one of the models, yielding an isotopy of  $S_j$  to one of the models.

The remaining cases, when  $S_j'$  has a local maximum or minimum or no critical points, are similar but simpler so we leave these cases to the reader.  $\square$

Now we can finish the proof of Alexander's Theorem, where the surface  $S$  is a sphere. Since every circle in a sphere separates the sphere into two components, each surgery splits one sphere into two spheres. Reversing the sequence of surgeries, we then start with a collection of spheres  $S_j$  bounding balls. The inductive assertion is that at each stage of the reversed surgery process, we have a collection of spheres each bounding a ball. For the inductive step we have two balls  $A$  and  $B$  bounded by the spheres  $\partial A$  and  $\partial B$  resulting from a surgery. Letting the  $\varepsilon$  for the surgery go to 0 isotopes  $A$  and  $B$  so that  $\partial A \cap \partial B$  equals the horizontal surgery disk  $D$ . There are two cases, up to changes in notation:

- (i)  $A \cap B = D$ , with pre-surgery sphere denoted  $\partial(A + B)$
- (ii)  $B \subset A$ , with pre-surgery sphere denoted  $\partial(A - B)$ .

Since  $B$  is a ball, the lemma below implies that  $A$  and  $A \pm B$  are diffeomorphic. Then since  $A$  is a ball, so is  $A \pm B$ , and the inductive step is completed.  $\square$

**Lemma 1.3.** *Given an  $n$ -manifold  $M$  and a ball  $B^{n-1} \subset \partial M$ , let the manifold  $N$  be obtained from  $M$  by attaching a ball  $B^n$  via an identification of a ball  $B^{n-1} \subset \partial B^n$  with the ball  $B^{n-1} \subset \partial M$ . Then  $M$  and  $N$  are diffeomorphic.*

**Proof:** Any two codimension-zero balls in a connected manifold are isotopic. Applying this fact to the given inclusion  $B^{n-1} \subset \partial B^n$  and using isotopy extension, we conclude that the pair  $(B^n, B^{n-1})$  is diffeomorphic to the standard pair. So there is an isotopy of  $\partial N$  to  $\partial M$  in  $N$ , fixed outside  $B^n$ , pushing  $\partial N - \partial M$  across  $B^n$  to  $\partial M - \partial N$ . By isotopy extension,  $M$  and  $N$  are then diffeomorphic.  $\square$

## Existence and Uniqueness of Prime Decompositions

Let  $M$  be a 3-manifold and  $S \subset M$  a surface which is properly embedded, i.e.,  $S \cap \partial M = \partial S$ , a transverse intersection. For the moment we do not assume  $S$  is connected. Deleting a small open tubular neighborhood  $N(S)$  of  $S$  from  $M$ , we obtain a 3-manifold  $M|S$  which we say is obtained from  $M$  by **splitting** along  $S$ . The neighborhood  $N(S)$  is an interval-bundle over  $S$ , so if  $M$  is orientable,  $N(S)$  is a product  $S \times (-\varepsilon, \varepsilon)$  if and only if  $S$  is orientable.

Now suppose that  $M$  is connected and  $S \subset M$  is a separating sphere, meaning that  $M|S$  has two components,  $M'_1$  and  $M'_2$ . Let  $M_i$  be obtained from  $M'_i$  by filling in its boundary sphere corresponding to  $S$  with a ball. In this situation we say  $M$  is the **connected sum**  $M_1 \# M_2$ . We remark that  $M_i$  is uniquely determined by  $M'_i$  since any two ways of filling in a ball  $B^3$  differ by a diffeomorphism of  $\partial B^3$ , and any

diffeomorphism of  $\partial B^3$  extends to a diffeomorphism of  $B^3$ . This last fact follows from the stronger assertion that any diffeomorphism of  $S^2$  is isotopic to either the identity or a reflection (orientation-reversing), and each of these two diffeomorphisms extends over a ball.

The connected sum operation is commutative by definition and has  $S^3$  as an identity since a decomposition  $M = M \# S^3$  is obtained by choosing the sphere  $S$  to bound a ball in  $M$ . The connected sum operation is also associative, since in a sequence of connected sum decompositions, e.g.,  $M_1 \# (M_2 \# M_3)$ , the later splitting spheres can be pushed off the balls filling in earlier splitting spheres, so one may assume all the splitting spheres are disjointly embedded in the original manifold  $M$ . Thus  $M = M_1 \# \cdots \# M_n$  means there is a collection  $S$  consisting of  $n - 1$  disjoint spheres such that  $M|S$  has  $n$  components  $M'_i$ , with  $M_i$  obtained from  $M'_i$  by filling in its boundary spheres corresponding to spheres of  $S$  with balls.

A connected 3-manifold  $M$  is called **prime** if  $M = P \# Q$  implies  $P = S^3$  or  $Q = S^3$ . For example, Alexander's theorem implies that  $S^3$  is prime, since every 2-sphere in  $S^3$  bounds a 3-ball. The latter condition, stronger than primeness, is called irreducibility:  $M$  is **irreducible** if every 2-sphere  $S^2 \subset M$  bounds a ball  $B^3 \subset M$ . The two conditions are in fact very nearly equivalent:

|| **Proposition 1.4.** *The only orientable prime 3-manifold which is not irreducible is  $S^1 \times S^2$ .*

**Proof:** If  $M$  is prime, every 2-sphere in  $M$  which separates  $M$  into two components bounds a ball. So if  $M$  is prime but not irreducible there must exist a nonseparating sphere in  $M$ . For a nonseparating sphere  $S$  in an orientable manifold  $M$  the union of a product neighborhood  $S \times I$  of  $S$  with a tubular neighborhood of an arc joining  $S \times \{0\}$  to  $S \times \{1\}$  in the complement of  $S \times I$  is a manifold diffeomorphic to  $S^1 \times S^2$  minus a ball. Thus  $M$  has  $S^1 \times S^2$  as a connected summand. Assuming  $M$  is prime, then  $M = S^1 \times S^2$ .

It remains to show that  $S^1 \times S^2$  is prime. Let  $S \subset S^1 \times S^2$  be a separating sphere, so  $S^1 \times S^2|S$  consists of two compact 3-manifolds  $V$  and  $W$  each with boundary a 2-sphere. We have  $\mathbb{Z} = \pi_1(S^1 \times S^2) \approx \pi_1 V * \pi_1 W$ , so either  $V$  or  $W$  must be simply-connected, say  $V$  is simply-connected. The universal cover of  $S^1 \times S^2$  can be identified with  $\mathbb{R}^3 - \{0\}$ , and  $V$  lifts to a diffeomorphic copy  $\tilde{V}$  of itself in  $\mathbb{R}^3 - \{0\}$ . The sphere  $\partial \tilde{V}$  bounds a ball in  $\mathbb{R}^3$  by Alexander's theorem. Since  $\partial \tilde{V}$  also bounds  $\tilde{V}$  in  $\mathbb{R}^3$  we conclude that  $\tilde{V}$  is a ball, hence also  $V$ . Thus every separating sphere in  $S^1 \times S^2$  bounds a ball, so  $S^1 \times S^2$  is prime.  $\square$

**Theorem 1.5.** *Each compact, connected, orientable 3-manifold  $M$  has a decomposition  $M = P_1 \# \cdots \# P_n$  with each  $P_i$  prime, and this decomposition is unique up to insertion or deletion of  $S^3$ 's and permutations of the factors  $P_i$ .*

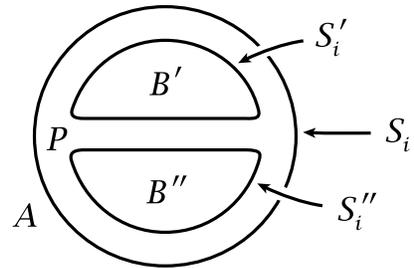

**Proof:** The existence of prime decompositions is harder than the uniqueness, so let us tackle the existence first. If  $M$  contains a nonseparating  $S^2$ , this gives a decomposition  $M = N \# S^1 \times S^2$  as we saw in the proof of Proposition 1.4. We can repeat this step of splitting off an  $S^1 \times S^2$  summand as long as we have nonseparating spheres, but the process cannot be repeated indefinitely since each  $S^1 \times S^2$  summand gives a  $\mathbb{Z}$  summand of  $H_1(M)$ , which is a finitely generated abelian group since  $M$  is compact. Thus it suffices to prove the existence of prime decompositions in the case that each 2-sphere in  $M$  separates. Each 2-sphere component of  $\partial M$  corresponds to a  $B^3$  summand of  $M$ , so we may also assume  $\partial M$  contains no 2-spheres.

We shall prove the following assertion, which clearly implies the existence of prime decompositions:

**Basic Fact.** *There is a bound on the number of spheres in a system  $S$  of finitely many disjoint spheres in  $M$  such that:*

(\*) *No component of  $M|S$  is a punctured 3-sphere, i.e., a compact manifold obtained from  $S^3$  by deleting the interiors of finitely many disjoint balls.*

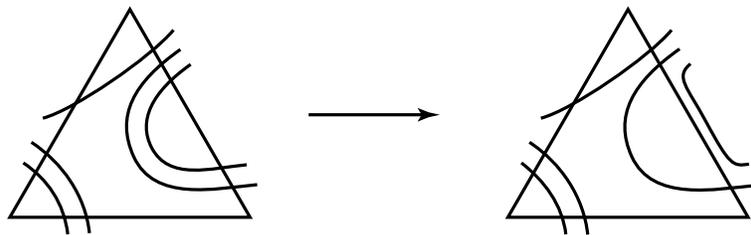

Before proving this we make a preliminary observation. Suppose the sphere system  $S$  satisfies (\*) and we do surgery on a sphere  $S_i$  of  $S$  using a disk  $D \subset M$  with  $D \cap S = \partial D \subset S_i$  to produce a pair a spheres  $S'_i$  and  $S''_i$ . Then at least one of the systems  $S'$  and  $S''$  obtained from  $S$  by replacing  $S_i$  with  $S'_i$  or  $S''_i$  again satisfies (\*). To see this, first perturb  $S'_i$  and  $S''_i$  to be disjoint from  $S_i$  and each other, with  $S_i$ ,  $S'_i$ , and  $S''_i$  together bounding a 3-punctured sphere  $P$ . On the other side of  $S_i$  from  $P$  we have a component  $A$  of  $M|S$ , while the spheres  $S'_i$  and  $S''_i$  split the component of  $M|S$  containing  $P$  into pieces  $B'$ ,  $B''$ , and  $P$ . Note that  $B'$  and  $B''$  are distinct, otherwise  $S'_i$  and  $S''_i$  would be nonseparating spheres in  $M$ . If both  $B'$  and  $B''$  were punctured spheres, then the component  $B' \cup B'' \cup P$  of  $M|S$  would be a punctured sphere, contrary to hypothesis. So one of  $B'$  and  $B''$ , say  $B'$ , is not a punctured sphere. If  $A \cup P \cup B''$  were a punctured sphere, this would force  $A$  to be a punctured sphere, by Alexander's theorem. This is also contrary to hypothesis. So we conclude that neither component of  $M|S'$  adjacent to  $S'_i$  is a punctured sphere, hence the sphere system  $S'$  satisfies (\*).

Now we begin to prove the assertion that the number of spheres in a system  $S$  satisfying (\*) is bounded. Choose a smooth triangulation  $\mathcal{T}$  of  $M$ . This has only finitely many simplices since  $M$  is compact. The given system  $S$  can be perturbed to be transverse to all the simplices of  $\mathcal{T}$ . This perturbation can be done inductively over the skeleta of  $\mathcal{T}$ : First make  $S$  disjoint from vertices, then transverse to edges, meeting them in finitely many points, then transverse to 2-simplices, meeting them in finitely many arcs and circles.

For a 3-simplex  $\tau$  of  $\mathcal{T}$ , we can make the components of  $S \cap \tau$  all disks, as follows. Such a component must meet  $\partial\tau$  by Alexander's theorem and condition (\*). Consider a circle  $C$  of  $S \cap \partial\tau$  which is innermost in  $\partial\tau$ . If  $C$  bounds a disk component of  $S \cap \tau$  we may isotope this disk to lie near  $\partial\tau$  and then proceed to a remaining innermost circle  $C$ . If an innermost remaining  $C$  does not bound a disk component of  $S \cap \tau$  we may surger  $S$  along  $C$  using a disk  $D$  lying near  $\partial\tau$  with  $D \cap S = \partial D = C$ , replacing  $S$  by a new system  $S'$  satisfying (\*), in which either  $C$  does bound a disk component of  $S' \cap \tau$  or  $C$  is eliminated from  $S' \cap \tau$ . After finitely many such steps we arrive at a system  $S$  with  $S \cap \tau$  consisting of disks, for each  $\tau$ . In particular, note that no component of the intersection of  $S$  with a 2-simplex of  $\mathcal{T}$  can be a circle, since this would bound disks in both adjacent 3-simplices, forming a sphere of  $S$  bounding a ball in the union of these two 3-simplices, contrary to (\*).

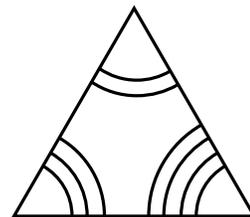

Next, for each 2-simplex  $\sigma$  we eliminate arc components of  $S \cap \sigma$  having both endpoints on the same edge of  $\sigma$ . Such an arc  $\alpha$  cuts off a disk  $D$  from  $\sigma$  which meets only one edge of  $\sigma$ . We may choose  $\alpha$  to be 'edgemoat', so that  $D$  contains no other arcs of  $S \cap \sigma$ , and hence  $D \cap S = \alpha$  since circles of  $S \cap \sigma$  have been eliminated in the previous step. By an isotopy of  $S$  supported near  $\alpha$  we then push the intersection arc  $\alpha$  across  $D$ , eliminating  $\alpha$  from  $S \cap \sigma$  and decreasing by two the number of points of intersection of  $S$  with the 1-skeleton of  $\mathcal{T}$ .

After such an isotopy decreasing the number of points of intersection of  $S$  with the 1-skeleton of  $\mathcal{T}$  we repeat the first step of making  $S$  intersect all 3-simplices in disks. This does not increase the number of intersections with the 1-skeleton, so after finitely many steps we arrive at the situation where  $S$  meets each 2-simplex only in

arcs connecting adjacent sides, and  $S$  meets 3-simplices only in disks.

Now consider the intersection of  $S$  with a 2-simplex  $\sigma$ . With at most four exceptions the complementary regions of  $S \cap \sigma$  in  $\sigma$  are rectangles with two opposite sides on  $\partial\sigma$  and the other two opposite sides arcs of  $S \cap \sigma$ . Thus if  $\mathcal{T}$  has  $t$  2-simplices, then all but at most  $4t$  of the components of  $M|S$  meet all the 2-simplices of  $\mathcal{T}$  only in such rectangles.

Let  $R$  be a component of  $M|S$  meeting all 2-simplices only in rectangles. For a 3-simplex  $\tau$ , each component of  $R \cap \partial\tau$  is an annulus  $A$  which is a union of rectangles. The two circles of  $\partial A$  bound disks in  $\tau$ , and  $A$  together with these two disks is a sphere bounding a ball in  $\tau$ , a component of  $R \cap \tau$  which can be written as  $D^2 \times I$  with  $\partial D^2 \times I = A$ . The  $I$ -fiberings of all such products  $D^2 \times I$  may be assumed to agree on their common intersections, the rectangles, to give  $R$  the structure of an  $I$ -bundle. Since  $\partial R$  consists of sphere components of  $S$ ,  $R$  is either the product  $S^2 \times I$  or the twisted  $I$ -bundle over  $\mathbb{R}P^2$ . (We can view  $R$  as the mapping cylinder of the associated  $\partial I$ -subbundle, a union of spheres which is a two-sheeted covering space of a connected base surface.) The possibility  $R = S^2 \times I$  is excluded by  $(*)$ . Each  $I$ -bundle  $R$  is thus the mapping cylinder of the covering space  $S^2 \rightarrow \mathbb{R}P^2$ . This is just  $\mathbb{R}P^3$  minus a ball, so each  $I$ -bundle  $R$  gives a connected summand  $\mathbb{R}P^3$  of  $M$ , hence a  $\mathbb{Z}_2$  direct summand of  $H_1(M)$ . Thus the number of such components  $R$  of  $M|S$  is bounded. Since the number of other components was bounded by  $4t$ , the number of components of  $M|S$  is bounded. Since every 2-sphere in  $M$  separates, the number of components of  $M|S$  is one more than the number of spheres in  $S$ . This finishes the proof of the existence of prime decompositions.

For uniqueness, suppose the nonprime  $M$  has two prime decompositions  $M = P_1 \# \cdots \# P_k \# \ell(S^1 \times S^2)$  and  $M = Q_1 \# \cdots \# Q_m \# n(S^1 \times S^2)$  where the  $P_i$ 's and  $Q_i$ 's are irreducible and not  $S^3$ . Let  $S$  be a disjoint union of 2-spheres in  $M$  reducing  $M$  to the  $P_i$ 's, by which we mean that the components of  $M|S$  are the manifolds  $P_1, \dots, P_k$  with punctures, plus possibly some punctured  $S^3$ 's. Such a system  $S$  exists: Take for example a collection of spheres defining the given prime decomposition  $M = P_1 \# \cdots \# P_k \# \ell(S^1 \times S^2)$  together with a nonseparating  $S^2$  in each  $S^1 \times S^2$ . Note that if  $S$  reduces  $M$  to the  $P_i$ 's, so does any system  $S'$  containing  $S$ .

Similarly, let  $T$  be a system of spheres reducing  $M$  to the  $Q_i$ 's. If  $S \cap T \neq \emptyset$ , we may assume this is a transverse intersection, and consider a circle of  $S \cap T$  which is innermost in  $T$ , bounding a disk  $D \subset T$  with  $D \cap S = \partial D$ . Using  $D$ , surger the sphere  $S_j$  of  $S$  containing  $\partial D$  to produce two spheres  $S'_j$  and  $S''_j$ , which we may

take to be disjoint from  $S_j$ , so that  $S_j$ ,  $S'_j$ , and  $S''_j$  together bound a 3-punctured 3-sphere  $P$ . By an earlier remark, the enlarged system  $S \cup S'_j \cup S''_j$  reduces  $M$  to the  $P_i$ 's. Deleting  $S_j$  from this enlarged system still gives a system reducing  $M$  to the  $P_i$ 's since this changes only one component of  $M|S \cup S'_j \cup S''_j$  by attaching  $P$  to one of its boundary spheres, which has the net effect of simply adding one more puncture to this component.

The new system  $S'$  meets  $T$  in one fewer circle, so after finitely many steps of this type we produce a system  $S$  disjoint from  $T$  and reducing  $M$  to the  $P_i$ 's. Then  $S \cup T$  is a system reducing  $M$  both to the  $P_i$ 's and to the  $Q_i$ 's. Hence  $k = m$  and the  $P_i$ 's are just a permutation of the  $Q_i$ 's.

Finally, to show  $\ell = n$ , we have  $M = N \# \ell(S^1 \times S^2) = N \# n(S^1 \times S^2)$ , so  $H_1(M) = H_1(N) \oplus \mathbb{Z}^\ell = H_1(N) \oplus \mathbb{Z}^n$ , hence  $\ell = n$ .  $\square$

The proof of the Prime Decomposition Theorem applies equally well to manifolds which are not just orientable, but oriented. The advantage of working with oriented manifolds is that the operation of forming  $M_1 \# M_2$  from  $M_1$  and  $M_2$  is well-defined: Remove an open ball from  $M_1$  and  $M_2$  and then identify the two resulting boundary spheres by an orientation-reversing diffeomorphism, so the orientations of  $M_1$  and  $M_2$  fit together to give a coherent orientation of  $M_1 \# M_2$ . The gluing map  $S^2 \rightarrow S^2$  is then uniquely determined up to isotopy, as we remarked earlier.

Thus to classify oriented compact 3-manifolds it suffices to classify the irreducible ones. In particular, one must determine whether each orientable irreducible 3-manifold possesses an orientation-reversing self-diffeomorphism.

To obtain a prime decomposition theorem for nonorientable manifolds requires very little more work. In Proposition 1.4 there are now two prime reducible manifolds,  $S^1 \times S^2$  and  $S^1 \tilde{\times} S^2$ , the nonorientable  $S^2$  bundle over  $S^1$ , which can also arise from a nonseparating 2-sphere. Existence of prime decompositions then works as in the orientable case. For uniqueness, one observes that  $N \# S^1 \times S^2 = N \# S^1 \tilde{\times} S^2$  if  $N$  is nonorientable. This is similar to the well-known fact in one lower dimension that connected sum of a nonorientable surface with the torus and with the Klein bottle give the same result. Uniqueness of prime decomposition can then be restored by replacing all the  $S^1 \times S^2$  summands in nonorientable manifolds with  $S^1 \tilde{\times} S^2$ 's.

A useful criterion for recognizing irreducible 3-manifolds is the following:

**|| Proposition 1.6.** *If  $p: \tilde{M} \rightarrow M$  is a covering space and  $\tilde{M}$  is irreducible, then so is  $M$ .*

The converse is also true, but its proof is more difficult and will be given in §3.1.

**Proof:** For a sphere  $S \subset M$  the covering space  $p^{-1}(S) \rightarrow S$  consists of disjoint lifts  $\tilde{S}$  of  $S$  projecting homeomorphically to  $S$ . Each of these lifts bounds a ball in  $\tilde{M}$  since  $\tilde{M}$  is irreducible. For a lift  $\tilde{S}$  bounding a ball  $B$  in  $\tilde{M}$ , any other lift of  $S$  in the interior of  $B$  bounds a ball in  $B$  by Alexander's Theorem, so we may choose  $\tilde{S}$  so that it is innermost in  $B$ , with no other lifts of  $S$  in the new ball  $B$  that it bounds.

We claim that  $p : B \rightarrow p(B)$  is a covering space. To verify the covering space property, consider first a point  $x \in p(B) - S$ , with  $U$  a small ball neighborhood of  $x$  disjoint from  $S$ . Then  $p^{-1}(U)$  is a disjoint union of balls in  $\tilde{M} - p^{-1}(S)$ , and the ones of these in  $B$  provide a uniform covering of  $U$  for the projection  $B \rightarrow p(B)$ . Now consider a point  $x \in S$ . For a small ball neighborhood  $U$  of  $x$  meeting  $S$  in a disk,  $p^{-1}(U)$  is a disjoint union of balls, only one of which,  $\tilde{U}$  say, meets  $B$  since no lifts of  $S$  lie in the interior of  $B$  and  $p$  is one-to-one on  $\tilde{S}$ . Therefore  $p$  restricts to a homeomorphism of  $\tilde{U} \cap B$  onto a neighborhood of  $x$  in  $p(B)$ . Thus the projection  $p : B \rightarrow p(B)$  is a covering space. This covering space is single-sheeted on  $\tilde{S}$ , hence on all of  $B$  since  $p(B)$  is connected, so  $p : B \rightarrow p(B)$  is a homeomorphism with image a ball bounded by  $S$ .  $\square$

By the proposition, manifolds with universal cover  $S^3$  are irreducible. This includes  $\mathbb{R}P^3$  and more generally each 3-dimensional lens space  $L_{p/q}$ , which is the quotient space of  $S^3$  under the free  $\mathbb{Z}_q$  action generated by the rotation  $(z_1, z_2) \mapsto (e^{2\pi i/q} z_1, e^{2p\pi i/q} z_2)$ , where  $S^3$  is viewed as the unit sphere in  $\mathbb{C}^2$ .

For a product  $M = S^1 \times F^2$ , or more generally any surface bundle  $F^2 \rightarrow M \rightarrow S^1$ , with  $F^2$  a compact connected surface other than  $S^2$  or  $\mathbb{R}P^2$ , the universal cover of  $M - \partial M$  is  $\mathbb{R}^3$ , so such an  $M$  is irreducible.

One might wonder whether there is an analogue of Proposition 1.6 with 'irreducible' replaced by 'prime', but there is a counterexample to this since  $S^1 \times S^2$  is a 2-sheeted covering space of  $\mathbb{R}P^3 \# \mathbb{R}P^3$ . Namely,  $\mathbb{R}P^3 \# \mathbb{R}P^3$  is the quotient of  $S^1 \times S^2$  under the identification  $(x, y) \sim (\rho(x), -y)$  with  $\rho$  a reflection of the circle. This quotient can also be described as the quotient of  $I \times S^2$  where  $(x, y)$  is identified with  $(x, -y)$  for  $x \in \partial I$ . In this description the 2-sphere giving the decomposition  $\mathbb{R}P^3 \# \mathbb{R}P^3$  is  $\{1/2\} \times S^2$ .

## Exercises

1. Prove the smooth Schoenflies theorem in  $\mathbb{R}^2$ : An embedded circle in  $\mathbb{R}^2$  bounds an embedded disk.
2. Show that for compact 3-manifold  $M$  there is a bound on the number of 2-spheres  $S_i$  which can be embedded in  $M$  disjointly such that no  $S_i$  bounds a ball and no two

$S_i$ 's bound a product  $S^2 \times I$ .

3. Use the method of proof of Alexander's theorem to show that every torus  $T \subset S^3$  bounds a solid torus  $S^1 \times D^2 \subset S^3$  on one side or the other. (This result is also due to Alexander.)

4. Develop an analogue of the prime decomposition theorem for splitting a compact irreducible 3-manifold along disks rather than spheres. In a similar vein, study the operation of splitting nonorientable manifolds along  $\mathbb{R}P^2$ 's with trivial normal bundles.

5. Show: If  $M^3 \subset \mathbb{R}^3$  is a compact submanifold with  $H_1(M) = 0$ , then  $\pi_1(M) = 0$ .

## 2. Torus Decomposition

Beyond the prime decomposition, there is a further canonical decomposition of irreducible compact orientable 3-manifolds, splitting along tori rather than spheres. This was discovered only in the mid 1970's, by Johannson and Jaco-Shalen, though in the simplified geometric version given here it could well have been proved in the 1930's. (A 1967 paper of Waldhausen comes very close to this geometric version.) Perhaps the explanation for this late discovery lies in the subtlety of the uniqueness statement. There are counterexamples to a naive uniqueness statement, involving a class of manifolds studied extensively by Seifert in the 1930's. The crucial observation, not made until the 1970's, was that these Seifert manifolds give rise to the only counterexamples. It then becomes possible to get a unique decomposition by treating the Seifert submanifolds in a given manifold as pieces that are to be left intact, and not decomposed.

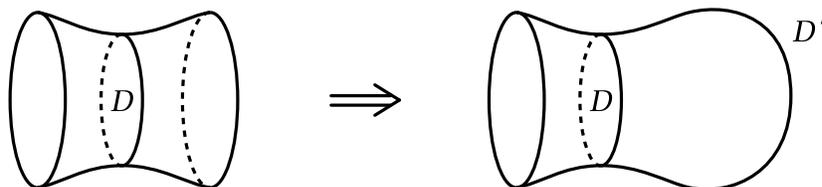

### Existence of Torus Decompositions

In this section and in later chapters we will often be dealing with surfaces in 3-manifolds, where by a **surface** in a 3-manifold  $M$  we will generally mean a compact connected surface  $S$  that is properly embedded in  $M$ , so  $S \cap \partial M = \partial S$ , a transverse intersection. A surface  $S \subset M$  is said to be **2-sided** if its normal bundle is trivial, and **1-sided** if its normal bundle is nontrivial. The 'sides' of  $S$  then correspond to the components of the complement of  $S$  in a tubular neighborhood.

For the torus decomposition of an irreducible manifold  $M$  the aim is to split  $M$  along a collection  $T$  of disjoint tori in  $M$  so that the resulting components of  $M|T$  are simpler than  $M$ . To do this we must impose some conditions on the tori, otherwise

the components of  $M|T$  could be more complicated than  $M$  rather than simpler. For example if one takes a knotted embedded  $S^1$  in  $S^3$  and splits  $S^3$  along the torus boundary  $T$  of a tubular neighborhood of the knot, then one component of  $S^3|T$  will be a solid torus  $S^1 \times D^2$  but the other component can be a fairly complicated nonsimply-connected manifold with torus boundary.

Examples like this will be excluded by the following general definition. A 2-sided surface  $S$  other than  $S^2$  or  $D^2$  in a 3-manifold  $M$  is **incompressible** if for each disk  $D \subset M$  with  $D \cap S = \partial D$  there is a disk  $D' \subset S$  with  $\partial D' = \partial D$ .

Thus, surgery on  $S$  along a disk in  $M$  cannot produce a simpler surface, but only splits off an  $S^2$  from  $S$ , leaving a diffeomorphic copy of  $S$  as the other piece resulting from the surgery. A disk  $D$  with  $D \cap S = \partial D$  will sometimes be called a **compressing disk** for  $S$ , whether or not a disk  $D' \subset S$  with  $\partial D' = \partial D$  exists. If  $S$  were a sphere or disk then the disk  $D'$  would always exist so every sphere or disk would satisfy the incompressibility condition, but it seems best to avoid this situation by excluding spheres and disks in the definition of incompressibility.

Before focusing our attention on incompressible tori we first develop a few basic facts about incompressible surfaces in general.

(1) A surface  $S \subset M$  which is not a sphere or disk is incompressible if the map  $\pi_1(S) \rightarrow \pi_1(M)$  induced by inclusion is injective. This is because if  $D$  is a compressing disk for  $S$  then  $\partial D$  is nullhomotopic in  $M$ , hence also in  $S$  if the map  $\pi_1(S) \rightarrow \pi_1(M)$  is injective. Then it is a standard fact in surface theory that a nullhomotopic embedded circle in a surface must bound a disk in the surface. This argument also works if one just assumes that the two inclusions of  $S$  into  $M|S$  on either side of  $S$  are injective on  $\pi_1$ .

The converse of (1) is true as well, but this is a more difficult result that will be proved in Chapter 3 as Corollary 3.3. For 1-sided surfaces these two conditions for incompressibility are no longer equivalent,  $\pi_1$ -injectivity being strictly stronger in general; see the exercises. However, the definition we have given requires incompressible surfaces to be 2-sided, so there should be no confusion on this point.

(2) There are no incompressible surfaces in  $\mathbb{R}^3$  or, equivalently, in  $S^3$ . This is imme-

diate from the converse to (1), but can also be proved directly, as follows. As we saw in the proof of Alexander's theorem, after isotopically perturbing a surface  $S \subset \mathbb{R}^3$  to make the height function a morse function with all critical points lying in different levels, there is a sequence of surgeries on  $S$  along horizontal disks converting  $S$  into a disjoint union of spheres. Surgery on an incompressible surface  $S$  in  $S^3$  using a compressing disk  $D$  splits  $S$  into two surfaces one of which is a sphere. This sphere bounds a ball on each side in  $S^3$ , and we can use the ball that is on the same side of  $S$  as  $D$  to isotope  $S$  to the other surface produced by the surgery. This surface is therefore incompressible. This argument applies to each of the surgeries that reduce the original incompressible surface  $S$  to a collection of spheres, so it follows that  $S$  is isotopic to one of these spheres, making  $S$  itself a sphere. However, the definition of incompressibility does not allow spheres, so we conclude that there are no incompressible surfaces in  $S^3$  or  $\mathbb{R}^3$ .

(3) A 2-sided torus  $T$  in a 3-manifold  $M$  is compressible if it bounds a solid torus  $S^1 \times D^2 \subset M$  or lies in a ball in  $M$ . The converse is also true if  $M$  is irreducible: A compressible torus in an irreducible manifold must either bound a solid torus or lie in a ball. For if  $T \subset M$  is a compressible torus there is a surgery on  $T$  along some disk  $D$  which turns  $T$  into a sphere. This sphere bounds a ball  $B \subset M$  if  $M$  is irreducible. There are now two cases: If  $B \cap D = \emptyset$  then reversing the surgery glues two disks in  $\partial B$  together to create a solid torus bounded by  $T$ . The other possibility is that  $D \subset B$ , and then  $T \subset B$ .

If  $M = S^3$  the ball  $B$  can be chosen disjoint from  $D$ , so the alternative  $D \subset B$  is not needed. Thus using statement (2) above we obtain the result, due to Alexander, that a torus in  $S^3$  bounds a solid torus on one side or the other.

(4) If  $S \subset M$  is a finite collection of disjoint incompressible surfaces, then  $M$  is irreducible if and only if  $M|S$  is irreducible. To see this, suppose first that  $M$  is irreducible. Then a 2-sphere in  $M|S$  bounds a ball in  $M$ , and this ball must be disjoint from  $S$  by statement (2) above, so the sphere bounds a ball in  $M|S$  and  $M|S$  is irreducible. Conversely, given a sphere  $S^2 \subset M$  which we may assume is transverse to  $S$ , consider a circle of  $S \cap S^2$  which is innermost in  $S^2$ , bounding a disk  $D \subset S^2$  with  $D \cap S = \partial D$ . By incompressibility of the components of  $S$ ,  $\partial D$  bounds a disk  $D' \subset S$ . The sphere  $D \cup D'$  bounds a ball  $B \subset M$  if  $M|S$  is irreducible. We must have  $B \cap S = D'$ , otherwise a component of  $S$  would be contained in  $B$ , contrary to statement (2). Isotoping  $S$  by pushing  $D'$  across  $B$  to  $D$  and slightly beyond eliminates the circle  $\partial D$  from  $S \cap S^2$ , along with any other circles of  $S \cap S^2$  which happen to lie

in  $D'$ . For the new  $S$  it is still true that  $M|S$  is irreducible since it is diffeomorphic to the old  $M|S$  by isotopy extension. We can then repeat this process of eliminating circles of  $S \cap S^2$  until we eventually get  $S \cap S^2 = \emptyset$ , or in other words  $S^2 \subset M|S$ . Since  $M|S$  is irreducible,  $S^2$  then bounds a ball in  $M|S$  and therefore also in  $M$ .

(5) If  $S \subset M$  is a finite collection of disjoint, properly embedded surfaces that are either incompressible or spheres or disks, then a surface  $T$  in  $M$  disjoint from  $S$  is incompressible in  $M$  if and only if it is incompressible in  $M|S$ . It is obvious that incompressibility in  $M$  implies incompressibility in  $M|S$ . For the less trivial converse, let  $D \subset M$  be a compressing disk for  $T$ . If this intersects  $S$ , we can assume the intersection is transverse, so  $D \cap S$  consists of circles in the interior of  $D$ . If any of these circles bound disks in  $S$ , we can take such a circle that is innermost in  $S$ , bounding a disk  $D_0 \subset S$  with  $D_0 \cap D = \partial D_0$ . We can use  $D_0$  to surger  $D$ , producing a new disk  $D$  intersecting  $S$  in fewer circles. After repeating this step a finite number of times, we may assume  $D \cap S$  contains no circles that bound disks in  $S$ . If there are any remaining circles in  $D \cap S$ , choose one that is innermost in  $D$ , bounding a disk  $D_0 \subset D$  with  $D_0 \cap S = \partial D_0$ . Since the components of  $S$  are either incompressible or spheres or disks, the circle  $\partial D_0$  must bound a disk in  $S$ , contrary to what we have arranged by the earlier surgery. Thus we must have  $D \cap S = \emptyset$ . Since  $T$  is incompressible in  $M|S$ , the circle  $\partial D$  then bounds a disk in  $T$ . This shows  $T$  is incompressible in  $M$ .

**Proposition 1.7.** *For a compact irreducible manifold  $M$  there is a bound on the number of components in a system  $S = S_1 \cup \cdots \cup S_n$  of disjoint closed incompressible surfaces  $S_i \subset M$  such that no component of  $M|S$  is a product  $T \times I$  with  $T$  a closed surface.*

**Proof:** This follows the scheme of the proof of existence of prime decompositions. First, perturb  $S$  to be transverse to a triangulation of  $M$  and perform the following two steps repeatedly to simplify the intersections of  $S$  with 2-simplices  $\sigma^2$  and 3-simplices  $\sigma^3$ :

(1) Make all components of  $S \cap \sigma^3$  disks. In the proof of prime decomposition, this was done by surgery, but now the surgeries can be achieved by isotopy. Namely, given a surgery disk  $D \subset M$  with  $D \cap S = \partial D$ , incompressibility gives a disk  $D' \subset S$  with  $\partial D' = \partial D$ . The sphere  $D \cup D'$  bounds a ball  $B \subset M$  since  $M$  is irreducible. We have  $B \cap S = D'$ , otherwise a component of  $S$  would lie in  $B$ . Then isotoping  $S$  by pushing  $D'$  across  $B$  to  $D$  and a little beyond replaces  $S$  by one of the two surfaces produced by the surgery.

Note that Step (1) eliminates circles of  $S \cap \sigma^2$ , since such a circle would bound disks in both adjacent  $\sigma^3$ 's, producing a sphere component of  $S$ .

(2) Eliminate arcs of  $S \cap \sigma^2$  with both endpoints on the same edge of  $\sigma^2$ . This can be done by isotopy of  $S$  just as in the prime decomposition theorem.

After these simplifications, components of  $M|S$  meeting 2-simplices only in rectangles are  $I$ -bundles as before. Trivial  $I$ -bundles are ruled out by hypothesis. The nontrivial  $I$ -bundles are bounded by surfaces  $S_i$  and are tubular neighborhoods of 1-sided surfaces  $S'_i$ . A surface  $S_i$  cannot have  $I$ -bundles on both sides since the union of these two  $I$ -bundles would be all of  $M$ , which is impossible since the  $I$ -bundles contain no vertices of the triangulation of  $M$ .

Replacing each  $S_i$  bounding an  $I$ -bundle by the corresponding  $S'_i$  converts  $S$  into a new system  $S'$  such that the components of  $M|S'$  are exactly the components of  $M|S$  that are not  $I$ -bundles. The number of components of  $M|S'$  is therefore bounded by four times the number of 2-simplices of the triangulation. Consider now the following exact sequence:

$$H_3(M, S'; \mathbb{Z}_2) \rightarrow H_2(S'; \mathbb{Z}_2) \rightarrow H_2(M; \mathbb{Z}_2)$$

By excision the first group can be replaced by  $H_3(M|S', \partial(M|S') - \partial M; \mathbb{Z}_2)$ . This is a vector space over  $\mathbb{Z}_2$  of dimension bounded by the number of components of  $M|S'$  since, after triangulating  $M|S'$ , there is at most one nontrivial simplicial relative 3-cycle with  $\mathbb{Z}_2$  coefficients in each component of  $M|S'$ . Thus the first and third terms of the exact sequence have dimensions bounded by numbers depending only on  $M$ , not  $S$ . By exactness the dimension of the middle term  $H_2(S'; \mathbb{Z}_2) \approx H_2(S; \mathbb{Z}_2)$  is also bounded. Thus the number of components of  $S'$  is bounded, and this is the same as the number of components of  $S$ .  $\square$

A properly embedded surface  $S \subset M$  is called  $\partial$ -**parallel** if it is isotopic, fixing  $\partial S$ , to a subsurface of  $\partial M$ . By isotopy extension this is equivalent to saying that  $S$  splits off a product  $S \times [0, 1]$  from  $M$  with  $S = S \times \{0\}$ . An irreducible manifold  $M$  is called **atoroidal** if every incompressible torus in  $M$  is  $\partial$ -parallel.

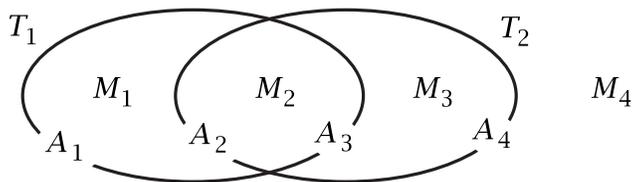

**Corollary 1.8.** *In a compact connected irreducible  $M$  there exists a (possibly empty) finite collection  $T$  of disjoint incompressible tori such that each component of  $M|T$  is atoroidal.*

**Proof:** If  $M$  is atoroidal we take  $T = \emptyset$ . Otherwise, let  $T_1$  be an incompressible torus in  $M$  that is not  $\partial$ -parallel. If  $M|T_1$  is atoroidal we take  $T = T_1$ , and otherwise we

let  $T_2$  be an incompressible torus in  $M|T_1$  that is not  $\partial$ -parallel. This process can be repeated as long as we do not obtain a splitting into atoroidal components, but this cannot be done infinitely often, otherwise we would have an arbitrarily large collection  $T$  of disjoint incompressible tori in  $M$  with no component of  $M|T$  a product of a torus with  $I$ , contradicting the previous proposition.  $\square$

Now we describe an example of an irreducible  $M$  where this torus decomposition into atoroidal pieces is not unique, the components of  $M|T$  for the two splittings being in fact nonhomeomorphic.

**Example.** For  $i = 1, 2, 3, 4$ , let  $M_i$  be a solid torus whose boundary torus is decomposed as the union of two annuli  $A_i$  and  $A'_i$  each winding  $q_i > 1$  times around the  $S^1$  factor of  $M_i$ . The union of these four solid tori, with each  $A'_i$  glued to  $A_{i+1}$  (subscripts mod 4), is the manifold  $M$ . This contains two tori  $T_1 = A_1 \cup A_3$  and  $T_2 = A_2 \cup A_4$ . The components of  $M|T_1$  are  $M_1 \cup M_2$  and  $M_3 \cup M_4$ , and the components of  $M|T_2$  are  $M_2 \cup M_3$  and  $M_4 \cup M_1$ .

The fundamental group of  $M_i \cup M_{i+1}$  has presentation  $\langle x_i, x_{i+1} \mid x_i^{q_i} = x_{i+1}^{q_{i+1}} \rangle$ . The center of this amalgamated free product is cyclic, generated by the element  $x_i^{q_i} = x_{i+1}^{q_{i+1}}$ . Factoring out the center gives quotient  $\mathbb{Z}_{q_i} * \mathbb{Z}_{q_{i+1}}$ , with abelianization  $\mathbb{Z}_{q_i} \oplus \mathbb{Z}_{q_{i+1}}$ . Thus if the  $q_i$ 's are for example distinct primes, then no two of the manifolds  $M_i \cup M_{i+1}$  are homeomorphic.

Results from later in this section will imply that  $M$  is irreducible,  $T_1$  and  $T_2$  are incompressible, and the four manifolds  $M_i \cup M_{i+1}$  are atoroidal. So the splittings  $M|T_1$  and  $M|T_2$ , though quite different, both satisfy the conclusions of the Corollary.

Manifolds like the ones in this example that are obtained by gluing together solid tori along annuli in their boundaries that are not contractible in the solid tori belong to a very special class of manifolds called Seifert manifolds, which we now define. A **model Seifert fibering** of  $S^1 \times D^2$  is a decomposition of  $S^1 \times D^2$  into disjoint circles, called **fibers**, constructed as follows. Starting with  $[0, 1] \times D^2$  decomposed into the segments  $[0, 1] \times \{x\}$ , identify the disks  $\{0\} \times D^2$  and  $\{1\} \times D^2$  via a  $2\pi p/q$  rotation, for  $p/q \in \mathbb{Q}$  with  $p$  and  $q$  relatively prime. The segment  $[0, 1] \times \{0\}$  then

becomes a fiber  $S^1 \times \{0\}$ , while every other fiber in  $S^1 \times D^2$  is made from  $q$  segments  $[0, 1] \times \{x\}$ . A **Seifert fibering** of a compact connected 3-manifold  $M$  is a decomposition of  $M$  into disjoint circles, the **fibers**, such that each fiber has a neighborhood diffeomorphic, preserving fibers, to a neighborhood of a fiber in some model Seifert fibering of  $S^1 \times D^2$ . A **Seifert manifold** is one which possesses a Seifert fibering.

Each fiber circle  $C$  in a Seifert fibering of a 3-manifold  $M$  has a well-defined **multiplicity**, the number of times a small disk transverse to  $C$  meets each nearby fiber. For example, in the model Seifert fibering of  $S^1 \times D^2$  with  $2\pi p/q$  twist, the fiber  $S^1 \times \{0\}$  has multiplicity  $q$  while all other fibers have multiplicity 1. Fibers of multiplicity 1 are **regular** fibers, and the other fibers are **multiple** (or **singular**, or **exceptional**). The multiple fibers are isolated and lie in the interior of  $M$ . The quotient space  $B$  of  $M$  obtained by identifying each fiber to a point is a surface, compact if  $M$  is compact, as is clear from the model Seifert fiberings. The projection  $\pi : M \rightarrow B$  is an ordinary fiber bundle on the complement of the multiple fibers. In particular,  $\pi : \partial M \rightarrow \partial B$  is a circle bundle, so  $\partial M$  consists of tori and Klein bottles, or just tori if  $M$  is orientable.

Somewhat surprisingly, Seifert manifolds account for *all* the nonuniqueness in torus decompositions of orientable 3-manifolds, according to the following theorem which will be the main result of this section.

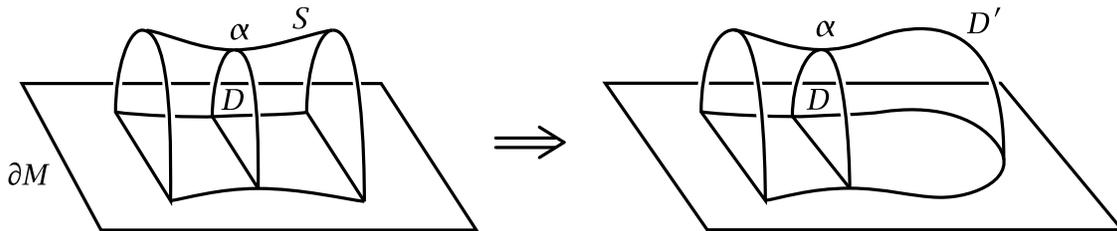

**Theorem 1.9.** *For a compact irreducible orientable 3-manifold  $M$  there exists a collection  $T \subset M$  of finitely many disjoint incompressible tori such that each component of  $M \setminus T$  is either atoroidal or a Seifert manifold, and a minimal such collection  $T$  is unique up to isotopy.*

Here ‘minimal’ means minimal with respect to inclusions of such collections. Note the strength of the uniqueness: up to isotopy, not just up to homeomorphism of  $M$ , for example. The orientability assumption can be dropped if splittings along incompressible Klein bottles are also allowed and the definition of ‘atoroidal’ is modified accordingly. For simplicity we will stick to the orientable case, however.

## Incompressible Surfaces in Seifert Manifolds

We have already proved the existence statement in the preceding theorem, where Seifert manifolds are unnecessary. We will prove the uniqueness statement using various facts about incompressible surfaces in Seifert manifolds which will be proved in this subsection. To state these we first need another definition. A properly embedded surface  $S \subset M$  is  **$\partial$ -incompressible** if for each disk  $D \subset M$  such that  $\partial D \cap S$  is an arc

$\alpha$  in  $\partial D$  and  $\partial D - \alpha \subset \partial M$  (such a  $D$  is called a  $\partial$ -**compressing disk** for  $S$ ) there is a disk  $D' \subset S$  with  $\alpha \subset \partial D'$  and  $\partial D' - \alpha \subset \partial M$ .

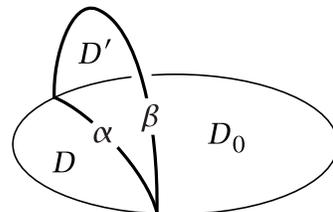

Analogously to the situation for incompressibility,  $S$  is  $\partial$ -incompressible if the map  $\pi_1(S, \partial S) \rightarrow \pi_1(M, \partial M)$  induced by inclusion is injective for all choices of basepoint in  $\partial S$ .

A surface which is either incompressible and  $\partial$ -incompressible, or a sphere not bounding a ball, or a disk that is not  $\partial$ -parallel, will be called an **essential** surface. For an essential surface  $S$  in an irreducible manifold  $M$  no circle of  $\partial S$  can bound a disk in  $\partial M$  since an innermost such disk could be pushed into the interior of  $M$  to give a compressing disk for  $S$ , forcing  $S$  itself to be a disk since surfaces are assumed to be connected, and then irreducibility of  $M$  would force the disk  $S$  to be  $\partial$ -parallel.

**Lemma 1.10.** *The only essential surfaces in  $S^1 \times D^2$  are disks isotopic to meridian disks  $\{x\} \times D^2$ .*

**Proof:** Let  $S$  be an essential surface in  $M = S^1 \times D^2$ . No circles of  $\partial S$  can bound disks in  $\partial M$  since an innermost such circle bounding a disk  $D \subset \partial M$  would bound a disk  $D' \subset S$  since  $S$  is essential, so  $S = D'$  and the sphere  $D \cup S$  would bound a ball in  $M$  since  $M$  is irreducible, making  $S$  a  $\partial$ -parallel disk. Thus we may isotope  $S$  so that all the circles of  $\partial S$  are either meridian circles  $\{x\} \times \partial D^2$  or transverse to all meridian circles. By a small perturbation  $S$  can also be made transverse to a fixed meridian disk  $D_0$ . Circles of  $S \cap D_0$  can be eliminated by pushing the disk  $D \subset S$  bounded by an innermost such circle  $C$  across the ball bounded by  $D$  and the disk in  $D_0$  bounded by  $C$ .

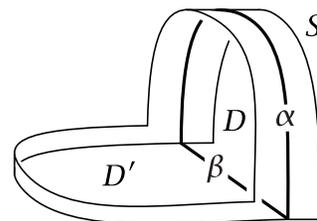

After this has been done, consider an edgemost arc  $\alpha$  of  $S \cap D_0$ . This cuts off a  $\partial$ -compressing disk  $D$  from  $D_0$ , so  $\alpha$  also cuts off a disk  $D'$  from  $S$ , meeting  $\partial M$  in an arc  $\beta$ . The existence of  $D'$  implies that the two ends of  $\beta$  lie on the same side of  $D_0$  in  $\partial M$ . But this is impossible since  $\beta$  is transverse to all meridians and therefore proceeds monotonically through the meridian circles of  $\partial M$ . Thus we must have  $S$  disjoint from  $D_0$ , so  $\partial S$  consists of meridian circles. Each circle of  $\partial S$  bounds a disk in the boundary sphere of the ball

$M|D_0$ . Pushing this disk slightly into the interior of the ball yields a compressing disk for  $S$  so since  $S$  is essential it must be a disk. It follows from Alexander's theorem that any two disks in a ball having the same boundary are isotopic fixing the boundary, so  $S$  is isotopic to a meridian disk in  $M$ .  $\square$

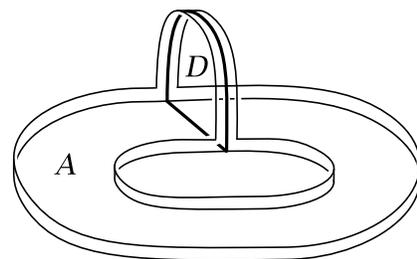

**Lemma 1.11.** *An incompressible surface  $S$  in an irreducible 3-manifold  $M$  with  $\partial S$  contained in torus boundary components of  $M$  is either  $\partial$ -incompressible or a  $\partial$ -parallel annulus.*

**Proof:** Suppose  $S$  is incompressible but  $\partial$ -compressible, with a  $\partial$ -compressing disk  $D$  meeting  $S$  in an arc  $\alpha$  which does not cut off a disk from  $S$ . Let  $\beta$  be the arc  $D \cap \partial M$ , lying in a torus component  $T$  of  $\partial M$ . The circles of  $\partial S$  in  $T$  do not bound disks in  $T$ , as noted before Lemma 1.10. Thus  $\beta$  lies in an annulus component  $A$  of  $T|\partial S$ . If  $\beta$  were trivial in  $A$ , cutting off a disk  $D'$ , incompressibility applied to the disk  $D \cup D'$  would imply that  $\alpha$  cuts off a disk from  $S$ , contrary to assumption. Therefore  $\beta$  must join the two components of  $\partial A$ .

If both components of  $\partial A$  come from the same circle of  $\partial S$  then  $S \cap T$  consists of a single circle. Since  $S$  is 2-sided, it has a nonvanishing normal vector field that points into  $D$  along  $\alpha$ . These normals point into  $\beta$  at the endpoints of  $\alpha$  and hence they point into  $A$  along the two circles of  $\partial A$ . But this is impossible if the two circles of  $\partial$  give the same circle of  $\partial S$ .

Thus the endpoints of  $\beta$  must lie in different circles of  $\partial S$ , and we have the configuration shown in the figure at the right. Let  $N$  be a neighborhood of  $\partial A \cup \alpha$  in  $S$ , a 3-punctured sphere. The circle  $\partial N - \partial S$  bounds an obvious disk in the complement of  $S$  lying near  $D \cup A$ , so since  $S$  is incompressible this boundary circle also bounds a disk in  $S$ . Thus  $S$  is an annulus. Surgering the torus  $S \cup A$  via  $D$  yields a sphere, which bounds a ball in  $M$  since  $M$  is irreducible. Hence  $S \cup A$  bounds a solid torus and  $S$  is  $\partial$ -parallel.  $\square$

**Proposition 1.12.** *If  $M$  is an irreducible Seifert-fibered manifold, then every essential surface in  $M$  is isotopic to a surface which is either **vertical**, i.e., a union of regular fibers, or **horizontal**, i.e., transverse to all fibers.*

**Proof:** Let  $C_1, \dots, C_n$  be fibers of the Seifert fibering which include all the multiple

fibers together with at least one regular fiber if there are no multiple fibers. Let  $M_0$  be  $M$  with small fibered open tubular neighborhoods of all the  $C_i$ 's deleted. Thus  $M_0$  is a circle bundle  $M_0 \rightarrow B_0$  over a compact surface  $B_0$  with nonempty boundary. Choose disjoint arcs in  $B_0$  whose union splits  $B_0$  into a disk, and let  $A$  be the pre-image in  $M_0$  of this collection of arcs, a union of disjoint vertical annuli in  $M_0$ . The manifold  $M_1 = M_0|A$  is then a circle bundle over a disk, hence a solid torus.

Let  $S$  be an essential surface in  $M$ , possibly a disk that is not  $\partial$ -parallel, but not a sphere since  $M$  is irreducible. The circles of  $\partial S$  are nontrivial in  $\partial M$  as noted before Lemma 1.10. The circles of  $\partial S$  can then be isotoped to be either vertical or horizontal in each component torus or Klein bottle of  $\partial M$ . Vertical circles of  $\partial S$  can be perturbed by isotopy to be disjoint from  $A$ . We may assume  $S$  meets the fibers  $C_i$  transversely, and hence meets the neighborhoods of these fibers in disks transverse to fibers. So the surface  $S_0 = S \cap M_0$  also has each of its boundary circles either horizontal or vertical.

Circles of  $S \cap A$  bounding disks in  $A$  can be eliminated by isotopy of  $S$  as usual. Arcs of  $S \cap A$  with both endpoints on the same component of  $\partial A$  can be eliminated as follows. An edgemoat such arc  $\alpha$  cuts off a disk  $D$  from  $A$ . If the two endpoints of  $\alpha$  lie in a component of  $\partial M_0 - \partial M$ , then  $S$  can be isotoped across  $D$  to eliminate two intersection points with a fiber  $C_i$ . The other possibility, that the two endpoints of  $\alpha$  lie in  $\partial M$ , cannot occur, for if it did, the disk  $D$  would be a  $\partial$ -compressing disk for  $S$  in  $M$ , a configuration ruled out by the monotonicity argument in Lemma 1.10, with the role of meridians in that argument now played by vertical circles.

So we may assume the components of  $S \cap A$  are either vertical circles or horizontal arcs. If we let  $S_1 = S_0|A$  in the solid torus  $M_1 = M_0|A$ , it follows that  $\partial S_1$  consists of horizontal or vertical circles in the torus  $\partial M_1$ . Obviously both types of circles cannot be present simultaneously. We may assume the components of  $S_1$  are incompressible in  $M_1$ . For let  $D \subset M_1$  be a compressing disk for a component  $S_1$ . After a perturbation this will intersect the other components of  $S_1$  transversely in circles in the interior of  $D$ , so let  $C$  be an innermost such circle. This bounds a disk  $D_0$  in  $S$ . If  $D_0$  is contained in  $M_1$  then we can use it to modify  $D$  to eliminate  $C$  from  $D \cap S_1$ . If  $D_0$  is not contained in  $M_1$  we can use it to isotope  $S$  to eliminate some components of  $\partial S_1$ . Repeating this argument, we can isotope  $S$  so that each component of  $S_1$  is either incompressible in  $M_1$  or a disk. In the latter case the disk cannot be  $\partial$ -parallel since its boundary is vertical or horizontal in  $\partial M_1$ .

Since the non-disk components of  $S_1$  are incompressible, each such component is either a  $\partial$ -parallel annulus or essential in  $M_1$ , hence isotopic to a meridian disk by

Lemma 1.10. If  $S_1$  contains a  $\partial$ -parallel annulus with horizontal boundary, then this annulus has a  $\partial$ -compressing disk  $D$  with  $D \cap \partial M_1$  a vertical arc in  $\partial M_0$ . As in the earlier step when we eliminated arcs of  $S \cap A$  with endpoints on the same component of  $\partial A$ , this leads to an isotopy of  $S$  removing intersection points with a fiber  $C_i$ . So we may assume all components of  $S_1$  are either  $\partial$ -parallel annuli with vertical boundary or disks with horizontal boundary.

Since vertical circles in  $\partial M_1$  cannot be disjoint from horizontal circles,  $S_1$  is either a union of  $\partial$ -parallel annuli with vertical boundary or a union of disks with horizontal boundary. In the former case  $S_1$  can be isotoped to be vertical, staying fixed on  $\partial S_1$  where it is already vertical. This isotopy gives an isotopy of  $S$  to a vertical surface. In the opposite case that  $S_1$  consists of disks with horizontal boundary, isotopic to meridian disks in  $M_1$ , we can isotope  $S_1$  to be horizontal fixing  $\partial S_1$ , and this gives an isotopy of  $S$  to a horizontal surface.  $\square$

Vertical surfaces are easy to understand: They are circle bundles since they are disjoint from multiple fibers by definition, hence they are either annuli, tori, or Klein bottles.

Horizontal surfaces are somewhat more subtle. For a horizontal surface  $S$  the projection  $\pi : S \rightarrow B$  onto the base surface of the Seifert fibering is a branched covering, with a branch point of multiplicity  $q$  for each intersection of  $S$  with a singular fiber of multiplicity  $q$ . (To see this, look in a neighborhood of a fiber, where the map  $S \rightarrow B$  is equivalent to the projection of a number of meridian disks onto  $B$ , clearly a branched covering.) For this branched covering  $\pi : S \rightarrow B$  there is a useful formula relating the Euler characteristics of  $S$  and  $B$ ,

$$\chi(B) - \chi(S)/n = \sum_i (1 - 1/q_i)$$

where  $n$  is the number of sheets in the branched cover and the multiple fibers of  $M$  have multiplicities  $q_1, \dots, q_m$ . To verify this formula, triangulate  $B$  so that the images of the multiple fibers are vertices, then lift this to a triangulation of  $S$ . Counting simplices would then yield the usual formula  $\chi(S) = n\chi(B)$  for an  $n$ -sheeted unbranched cover. In the present case, however, a vertex in  $B$  which is the image of a fiber of multiplicity  $q_i$  has  $n/q_i$  pre-images in  $S$ , rather than  $n$ . This yields a modified formula  $\chi(S) = n\chi(B) + \sum_i (-n + n/q_i)$ , which is equivalent to the one above.

There is further structure associated to a horizontal surface  $S$  in a Seifert-fibered manifold  $M$ . We may assume  $S$  is 2-sided since if it is 1-sided, it has an  $I$ -bundle

neighborhood whose boundary is a horizontal 2-sided surface. The projection  $S \rightarrow B$  is onto so  $S$  meets all fibers of  $M$ , and  $M|S$  is an  $I$ -bundle. (The local triviality of this  $I$ -bundle is clear if one looks in a model-fibered neighborhood of a fiber.) The associated  $\partial I$ -subbundle consists of two copies of  $S$ , so the  $I$ -bundle is the mapping cylinder of a 2-sheeted covering projection  $S \amalg S \rightarrow T$  for some possibly disconnected surface  $T$ . There are two cases, according to whether  $S$  separates  $M$  or not:

(1) If  $M|S$  is connected, so is  $T$ , and  $S \amalg S \rightarrow T$  is the trivial covering  $S \amalg S \rightarrow S$ , so  $M|S = S \times I$  and hence  $M$  is a bundle over  $S^1$  with fiber  $S$ . The surface fibers of this bundle are all horizontal surfaces in the Seifert fibering.

(2) If  $M|S$  has two components, each is a twisted  $I$ -bundle over a component  $T_i$  of  $T$ , the mapping cylinder of a nontrivial 2-sheeted covering  $S \rightarrow T_i$ ,  $i = 1, 2$ . The parallel copies of  $S$  in these mapping cylinders, together with  $T_1$  and  $T_2$ , are the leaves of a foliation of  $M$ . These leaves are the ‘fibers’ of a natural projection  $p: M \rightarrow I$ , with  $T_1$  and  $T_2$  the pre-images of the endpoints of  $I$ . This ‘fiber’ structure on  $M$  is not exactly a fiber bundle, so let us give it a new name: a **semi-bundle**. Thus a semi-bundle  $p: M \rightarrow I$  is the union of two twisted  $I$ -bundles  $p^{-1}[0, 1/2]$  and  $p^{-1}[1/2, 1]$  glued together by a homeomorphism of the fiber  $p^{-1}(1/2)$ . For example, in one lower dimension, the Klein bottle is a semi-bundle with fibers  $S^1$ , since it splits as the union of two Möbius bands. More generally, one could define semi-bundles with base any manifold with boundary.

The techniques we have been using can also be applied to determine which Seifert manifolds are irreducible:

**Proposition 1.13.** *A Seifert-fibered manifold  $M$  is irreducible unless it is  $S^1 \times S^2$ ,  $S^1 \tilde{\times} S^2$ , or  $\mathbb{R}P^3 \# \mathbb{R}P^3$ .*

**Proof:** We begin by observing that if  $M$  is reducible then there is a horizontal sphere in  $M$  not bounding a ball. This is proved by imitating the argument of the preceding proposition, with  $S$  now a sphere not bounding a ball in  $M$ . The only difference is that when incompressibility was used before, e.g., to eliminate trivial circles of  $S \cap A$ , we must now use surgery rather than isotopy. Such surgery replaces  $S$  with a pair of spheres  $S'$  and  $S''$ . If both  $S'$  and  $S''$  bounded balls, so would  $S$ , as we saw in the proof of Alexander’s theorem, so we may replace  $S$  by one of  $S'$ ,  $S''$  not bounding a ball. With these modifications in the proof, we eventually get a sphere which is either horizontal or vertical, but the latter cannot occur since  $S^2$  is not a circle bundle.

If  $S$  is a horizontal sphere in  $M$ , then as we have seen,  $M$  is either a sphere bundle or a sphere semi-bundle. The only two sphere bundles are  $S^1 \times S^2$  and  $S^1 \tilde{\times} S^2$ . A

sphere semi-bundle is two copies of the twisted  $I$ -bundle over  $\mathbb{R}P^2$  glued together via a diffeomorphism of  $S^2$ . Such a diffeomorphism is isotopic to either the identity or the antipodal map. The antipodal map extends to a diffeomorphism of the  $I$ -bundle  $\mathbb{R}P^2 \tilde{\times} I$ , so both gluings produce the same manifold,  $\mathbb{R}P^3 \# \mathbb{R}P^3$ .  $\square$

The manifolds  $S^1 \times S^2$ ,  $S^1 \tilde{\times} S^2$ , and  $\mathbb{R}P^3 \# \mathbb{R}P^3$  have Seifert fiberings. This is obviously true for  $S^1 \times S^1$ , while for  $S^1 \tilde{\times} S^2$  we can regard this as  $S^2 \times I$  with the two ends identified via the antipodal map of  $S^2$ , so the  $I$ -bundle structure on  $S^2 \times I$  gives  $S^1 \tilde{\times} S^2$  a circle bundle structure. For  $\mathbb{R}P^3 \# \mathbb{R}P^3$ , the  $I$ -bundle structures on the two halves  $\mathbb{R}P^2 \tilde{\times} I$  of  $\mathbb{R}P^3 \# \mathbb{R}P^3$  are glued together by the identity so they give  $\mathbb{R}P^3 \# \mathbb{R}P^3$  a circle bundle structure too.

Now we can give a converse to Proposition 1.12:

**Proposition 1.14.** *Let  $M$  be an irreducible Seifert-fibered 3-manifold. Then every 2-sided horizontal surface  $S \subset M$  is essential. The same is true of every 2-sided vertical surface except:*

- (a) *a torus bounding a solid torus with a model Seifert fibering, containing at most one multiple fiber, or*
- (b) *an annulus cutting off a solid torus from  $M$  with the product fibering on this solid torus.*

**Proof:** For a 2-sided horizontal surface  $S$  we have noted that the Seifert fibering induces an  $I$ -bundle structure on  $M|S$ , so  $M|S$  is the mapping cylinder of a 2-sheeted covering  $S \amalg S \rightarrow T$ . In the special case that  $S$  is a disk, the only 2-sheeted covering  $D^2 \amalg D^2 \rightarrow T$  is the trivial covering  $D^2 \amalg D^2 \rightarrow D^2$  so the  $I$ -bundle  $M|S$  is  $D^2 \times I$ . Since  $S$  does not separate  $M$  it cannot be  $\partial$ -parallel, so  $S$  is essential in this case.

If  $S$  is a horizontal surface other than a disk we need to show that it is incompressible and  $\partial$ -incompressible. The covering space projection  $S \amalg S \rightarrow T$  is injective on  $\pi_1$  for all choices of a basepoint in  $S \amalg S$ , so the inclusion of the  $\partial I$ -subbundle into the  $I$ -bundle is also injective on  $\pi_1$ , which implies that  $S$  is incompressible. Similarly,  $\partial$ -incompressibility follows from injectivity of relative  $\pi_1$ 's.

Now let  $S$  be a 2-sided vertical surface, so  $S$  is a circle bundle over a 1-manifold, hence a torus, Klein bottle, or annulus. Suppose first that  $S$  is a torus or Klein bottle. If  $S$  is compressible, choose a compressing disk  $D$  with  $\partial D$  not bounding a disk in  $S$ . Then  $D$  is essential in  $M|S$ . The components of the Seifert-fibered manifold  $M|S$  are irreducible by Proposition 1.13 since they have nonempty boundary, so  $D$  can be isotoped in  $M|S$  to be horizontal by Proposition 1.12, as a disk cannot be vertical.

The Euler characteristic formula in the component of  $M|S$  containing  $D$  takes the form  $\chi(B) - 1/n = \sum_i(1 - 1/q_i)$  where  $n$  is the number of sheets in the branched cover  $D \rightarrow B$  and there is one term in the summation for each multiple fiber. The summation is non-negative so  $\chi(B) > 0$ . Since  $\partial B$  is nonempty,  $B$  must then be a disk with  $\chi(B) = 1$ . Each term  $1 - 1/q_i$  is at least  $1/2$ , so there can be at most one such term, and so there is at most one multiple fiber. This component of  $M|S$  is therefore a solid torus with a model Seifert fibering, and  $S$  is its torus boundary.

In the case that  $S$  is a vertical annulus, a compressing disk  $D$  with  $\partial D$  not bounding a disk in  $S$  can be isotoped to have  $\partial D$  vertical in  $S$ . Then  $D$  is essential in  $M|S$  and so can be isotoped in  $M|S$  to be horizontal, so in particular  $\partial D$  becomes horizontal, but this is impossible since  $\partial D$  is vertical. Thus  $S$  must be incompressible. If it is  $\partial$ -compressible it must be  $\partial$ -parallel by Lemma 1.11, cutting off a Seifert-fibered solid torus from  $M$ . The Seifert fibering of this solid torus is a model Seifert fibering as we argued in the preceding paragraph, but it cannot contain a multiple fiber since the annulus  $S$  in its boundary wraps around the solid torus only once, as the solid torus is  $S \times I$  with  $S = S \times \{0\}$ . This shows that if  $S$  is not essential, it cuts off a solid torus from  $M$  with the product fibering.  $\square$

The Euler characteristic argument in this proof showed the following fact:

|| **Corollary 1.15.** *The only Seifert fiberings of  $S^1 \times D^2$  are the model Seifert fiberings.*

## Uniqueness of Torus Decompositions

For the proof of the uniqueness statement in Theorem 1.9 we will need three preliminary lemmas.

|| **Lemma 1.16.** *An essential annulus in a Seifert-fibered manifold  $M$  can be isotoped to be vertical, after possibly changing the Seifert fibering if  $M$  is an  $I$ -bundle over the torus or Klein bottle.*

**Proof:** By Proposition 1.12 an essential annulus  $A$  in  $M$  can be isotoped to be either horizontal or vertical, so let us assume  $A$  is horizontal. If  $A$  does not separate  $M$  then  $M|A$  is the product  $A \times I$ , so  $M$  is a bundle over  $S^1$  with fiber  $A$ , the mapping torus  $A \times I / \{(x, 0) \sim (\varphi(x), 1)\}$  of a diffeomorphism  $\varphi : A \rightarrow A$ . We can view  $A \times I$  as a cube with left and right faces identified by translation and then  $M$  is obtained by further identifying the top and bottom faces via  $\varphi$ . The top and bottom faces become the annulus  $A$ . There are only four isotopy classes of diffeomorphisms of  $A = S^1 \times I$ ,

obtained as the composition of either the identity or a reflection in each factor, so  $M$  can be obtained as the mapping torus one of these four diffeomorphisms. Since these diffeomorphisms preserve the product structure on  $A = S^1 \times I$ , we can construct another Seifert fibering of  $M$  by fibering the cube by parallel line segments joining the left and right faces. In this fibering of  $M$  the annulus  $A$  is vertical. Fibering the cube by segments joining the front and back faces then gives an  $I$ -bundle structure on  $M$ . The four choices of diffeomorphisms of  $A$  give the two  $I$ -bundles over the torus and the two  $I$ -bundles over the Klein bottle.

If  $A$  is separating,  $M|A$  consists of two copies of the twisted  $I$ -bundle  $B$  over a Möbius band obtained from a cube by identifying the left and right faces by a 180 degree twist. The annulus  $A$  is formed by the top and bottom faces of the cube. All four possible gluings of the two copies of  $B$  yield the same manifold  $M$  since the gluing maps extend over  $B$ . The fibering of the cube by segments joining the left and right faces gives a model Seifert fibering of the solid torus  $B$  with a multiple fiber of multiplicity 2. After gluing the two copies of  $B$  together one has a Seifert fibering of  $M$  in which  $A$  is vertical. (This Seifert fibering has base space a disk with two multiple fibers of multiplicity 2.) Fibering the two cubes by segments joining the front and back faces makes  $M$  the twisted  $I$ -bundle over the Klein bottle obtained by gluing two Möbius bands together along their boundaries.  $\square$

**Lemma 1.17.** *If  $M$  is a Seifert manifold then the restrictions to  $\partial M$  of any two Seifert fiberings of  $M$  are isotopic unless  $M$  is  $S^1 \times D^2$  or an  $I$ -bundle over the torus or Klein bottle.*

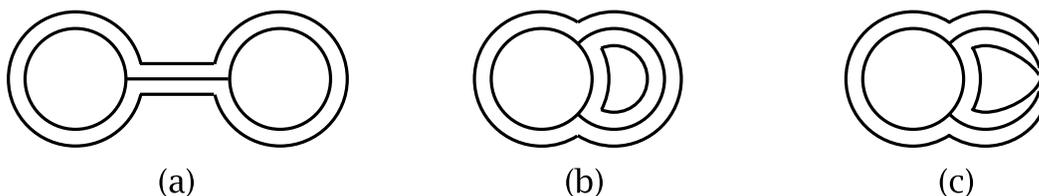

**Proof:** Let  $M$  be Seifert-fibered with  $\partial M \neq \emptyset$ . First we note that  $M$  contains an essential vertical annulus  $A$  unless  $M = S^1 \times D^2$ . Namely, take  $A = \pi^{-1}(\alpha)$  where  $\alpha$  is an arc in the base surface  $B$  which is disjoint from the images of the multiple fibers and is either nonseparating (if  $B \neq D^2$ ) or separates the images of multiple fibers (if  $B = D^2$  and there are at least two multiple fibers). This guarantees that  $A$  is essential by Proposition 1.14. If  $M$  is not an  $I$ -bundle over the torus or Klein bottle then by Lemma 1.16,  $A$  is isotopic to a vertical annulus in any other Seifert fibering of  $M$ , so the two Seifert fiberings can be isotoped to agree on  $\partial A$ , hence on the components of  $\partial M$  containing  $\partial A$ . Since  $\alpha$  could be chosen to meet any component of  $\partial B$ , the result follows.  $\square$

**Lemma 1.18.** *If  $M$  is compact, orientable, irreducible, and atoroidal, and  $M$  contains an essential annulus meeting only torus components of  $\partial M$ , then  $M$  is a Seifert manifold.*

**Proof:** Let  $A$  be an annulus as in the hypothesis. Since we assume  $M$  is orientable there are just three possibilities:

- (a)  $A$  meets two different tori  $T_1$  and  $T_2$  in  $\partial M$ , and  $A \cup T_1 \cup T_2$  has a neighborhood  $N$  which is a product of a 2-punctured disk with  $S^1$ .
- (b)  $A$  meets only one torus  $T_1$  in  $\partial M$ , the union of  $A$  with either annulus of  $T_1 \mid \partial A$  is a torus, and  $A \cup T_1$  has a neighborhood  $N$  which is a product of a 2-punctured disk with  $S^1$ .
- (c)  $A$  meets only one torus  $T_1$  in  $\partial M$ , the union of  $A$  with either annulus of  $T_1 \mid \partial A$  is a Klein bottle, and  $A \cup T_1$  has a neighborhood  $N$  which is an  $S^1$  bundle over a punctured Möbius band.

In all three cases  $N$  has the structure of a circle bundle  $N \rightarrow B$  with  $A$  vertical.

By hypothesis, the tori of  $\partial N - \partial M$  must either be compressible or  $\partial$ -parallel in  $M$ . Suppose  $D$  is a nontrivial compressing disk for  $\partial N - \partial M$  in  $M$ , with  $\partial D$  a nontrivial loop in a component torus  $T$  of  $\partial N - \partial M$ . If  $D \subset N$ , then  $N$  would be a solid torus  $S^1 \times D^2$  by Proposition 1.14, which is impossible since  $N$  has more than one boundary torus. So  $D \cap N = \partial D$ . Surgering  $T$  along  $D$  yields a 2-sphere bounding a ball  $B^3 \subset M$ . This  $B^3$  lies on the opposite side of  $T$  from  $N$ , otherwise we would have  $N \subset B^3$  with  $T$  the only boundary component of  $N$ . Reversing the surgery,  $B^3$  becomes a solid torus outside  $N$ , bounded by  $T$ .

The other possibility for a component  $T$  of  $\partial N - \partial M$  is that it is  $\partial$ -parallel in  $M$ , cutting off a product  $T \times I$  from  $M$ . This  $T \times I$  cannot be  $N$  since  $\pi_1 N$  is non-abelian, the map  $\pi_1 N \rightarrow \pi_1 B$  induced by the circle bundle  $N \rightarrow B$  being a surjection to a free group on two generators. So  $T \times I$  is an external collar on  $N$ , and hence can be absorbed into  $N$ .

Thus  $M$  is  $N$  with solid tori perhaps attached to one or two tori of  $\partial N - \partial M$ . The meridian circles  $\{x\} \times \partial D^2$  in such attached  $S^1 \times D^2$ 's are not isotopic in  $\partial N$  to circle fibers of  $N$ , otherwise  $A$  would be compressible in  $M$  (recall that  $A$  is vertical in  $N$ ). Thus the circle fibers wind around the attached  $S^1 \times D^2$ 's a nonzero number of times in the  $S^1$  direction. Hence the circle bundle structure on  $N$  extends to model Seifert fiberings of these  $S^1 \times D^2$ 's, and so  $M$  is Seifert-fibered.  $\square$

**Proof of Theorem 1.9:** Only the uniqueness statement remains to be proved. Let  $T = T_1 \cup \cdots \cup T_m$  and  $T' = T'_1 \cup \cdots \cup T'_n$  be two minimal collections of disjoint incompressible tori splitting  $M$  into manifolds  $M_j$  and  $M'_j$ , respectively, which are either atoroidal or Seifert-fibered. We may suppose  $T$  and  $T'$  are nonempty, otherwise the theorem is trivial since if  $T$  is empty for example,  $M$  itself would be Seifert-fibered or atoroidal and the minimality of  $T'$  would force it to be empty as well. We can also assume no torus of  $T$  is isotopic to a torus of  $T'$ , otherwise we could extend this isotopy to an ambient isotopy of  $M$  and in particular of  $T$ , to make  $T$  and  $T'$  have a torus in common, then split  $M$  along this torus and appeal to induction on the number of tori in  $T$  and  $T'$ .

After perturbing  $T$  to meet  $T'$  transversely, we can isotope  $T$  or  $T'$  to eliminate circles of  $T \cap T'$  which bound disks in  $T$  or  $T'$  by the usual argument using incompressibility and irreducibility.

For each component  $M_j$  of  $M|T$  the components of  $T' \cap M_j$  are then tori or annuli. To see that the annulus components are incompressible in  $M_j$ , let  $D$  be a compressing disk in  $M_j$  for an annulus component  $A$  of  $T' \cap M_j$ . After perturbing  $D$  to be transverse to  $T'$ , it might have circles of intersection with  $T'$  in its interior, but these can be eliminated, innermost first, by an isotopy of  $D$  in  $M$  fixing  $\partial D$  since the components of  $T'$  are incompressible in  $M$ . After this has been done,  $D$  will be a compressing disk for  $A$  in  $M$  and hence also for the component torus of  $T'$  containing  $A$ . This torus is incompressible in  $M$ , so  $\partial D$  bounds a disk  $D'$  in  $T'$ . This disk must be disjoint from  $T$  since we have eliminated trivial circles of  $T \cap T'$ . Thus  $D'$  is contained in  $M_j$ . It must in fact be contained in  $A$ , otherwise  $A$  would be contained in  $D'$  and  $T \cap T'$  would contain a circle that is trivial in  $T'$ . This shows  $A$  is incompressible in  $M_j$ . If it is  $\partial$ -compressible then it is  $\partial$ -parallel by Lemma 1.11, so it can be eliminated by an isotopy of  $T'$  decreasing the number of circles of  $T \cap T'$ . Thus we can assume all annulus components of  $T' \cap M_j$  are essential in  $M_j$  for all  $j$ .

A circle  $C$  of  $T \cap T'$  lies in the boundary of annulus components  $A_j$  of  $T' \cap M_j$  and  $A_k$  of  $T' \cap M_k$  (possibly  $A_j = A_k$  if  $M_j = M_k$ ). By Lemma 1.18  $M_j$  and  $M_k$  are Seifert-fibered. Our next goal is to use minimality of the collection  $T$  to show that it must now be disjoint from  $T'$ . To do this we distinguish several cases:

1. If  $M_j \neq M_k$ , Lemma 1.16 implies that we can choose Seifert fiberings of  $M_j$  and  $M_k$  in which  $A_j$  and  $A_k$  can be isotoped to be vertical. Extending these isotopies to ambient isotopies and reversing the time parameter gives isotopies of the Seifert fiberings to new Seifert fiberings in which the original  $A_j$  and  $A_k$  are vertical. These

Seifert fiberings both have  $C$  as a fiber, so they can be isotoped to agree on the torus component  $T_i$  of  $T$  containing  $C$ . This means that the collection  $T$  is not minimal since  $T_i$  could be deleted from it. Thus the case  $M_j \neq M_k$  cannot occur.

2. The same argument works if  $M_j = M_k$  and  $A_j = A_k$ , so we may assume now that  $M_j = M_k$  and  $A_j \neq A_k$ .

3. If  $M_j$  is not one of the  $I$ -bundles in Lemma 1.16 then  $A_j$  can be isotoped to be vertical in  $M_j$ , and the same is true for  $A_k$ . Restricting these two isotopies to the two copies of  $C$  in  $M_j$  on either side of  $T_i$ , we then have two isotopic circles in  $T_i$  that are vertical in the Seifert fibering of  $M_j$ . This implies that the Seifert fibering can be isotoped to extend across  $T_i$  and so the collection  $T$  would again fail to be minimal.

4. If  $M_j$  is one of the  $I$ -bundles in Lemma 1.16 it can only be the trivial bundle  $S^1 \times S^1 \times I$  since  $M_j$  is orientable and has at least two boundary components, coming from the two sides of  $T_i$ . If  $M_j = S^1 \times S^1 \times I$  and we have to rechoose the Seifert fibering of  $M_j$  to make  $A_j$  vertical, then as we saw in the proof of Lemma 1.16, the new fibering is the trivial circle bundle over  $S^1 \times I$ . The annulus  $A_j$ , being vertical in this fibering and essential in  $M_j$ , must then join the two boundary tori of  $M_j$  since its projection to the base surface  $S^1 \times I$  of the circle bundle must be an arc joining the two boundary components of  $S^1 \times I$ . The boundary circle of  $T_k$  coming from  $C$  is disjoint from  $A_j$  so it can be isotoped in  $T_i$  to be vertical. This implies that the Seifert fibering of  $M_j$  can be isotoped, fixing  $A_j$ , first to make this boundary circle of  $T_k$  vertical and then to make the two fiberings of  $T_i$  coming from either side in  $M_j$  agree, so  $T_i$  could be omitted from  $T$ . The same argument would work if the roles of  $T_j$  and  $T_k$  are reversed.

5. The only remaining possibility is that  $M_j = S^1 \times S^1 \times I$  and both  $T_j$  and  $T_k$  can be isotoped to be vertical in  $M_j$ . The argument in Case 3 then applies.

Thus we may assume  $T \cap T' = \emptyset$ . If any component  $T_i$  of  $T$  lies in an atoroidal  $M'_j$  it must be isotopic to a component  $T'_i$  of  $T'$ , a situation we have already excluded. Thus we may assume each  $T_i$  lies in a Seifert-fibered  $M'_j$ , and similarly, each  $T'_i$  lies in a Seifert-fibered  $M_j$ . These Seifert-fibered manifolds all have nonempty boundary, so they contain no horizontal tori. Thus we may assume all the tori  $T_i \subset M'_j$  and  $T'_i \subset M_j$  are vertical.

We can also assume all the  $M_j$ 's and  $M'_j$ 's are Seifert-fibered by the following argument. An atoroidal  $M_j$ , for example, would have to lie entirely within an  $M'_j$ , as  $M_j$  contains no  $T'_i$ 's. This  $M'_j$  would have to be Seifert-fibered since it contains the

$T_i$ 's in  $\partial M_j$ . Then since the  $T_i$ 's in  $\partial M_j$  are vertical in  $M'_j$ , the Seifert-fiberings of  $M'_j$  restricts to a Seifert-fiberings of  $M_j$ .

The  $T_i$ 's and  $T'_i$ 's together cut  $M$  into pieces  $N_p$ . Each  $N_p$  has two possibly different Seifert-fiberings, the one from the  $M_j$  which contains it, the other from the  $M'_j$  which contains it. Consider a torus  $T_i$ . This has four fiberings from the two Seifert-fiberings on the  $N_p$  and  $N_q$  on either side of it (possibly  $N_p = N_q$ ). Two of these fiberings of  $T_i$  must be equal since they come from the same  $M'_j$  containing  $T_i$ . We will show that the Seifert-fiberings of the  $M_j$  containing  $N_p$  and the  $M_k$  containing  $N_q$  (possibly  $M_j = M_k$ ) can be made to agree on  $T_i$ . But this would contradict the minimality of the collection  $T$  since  $T_i$  could be deleted from it.

In most cases the two Seifert-fiberings of  $N_p$  can be made to agree on  $T_i$  by an isotopy of the Seifert-fiberings of  $M_j$  supported near  $T_i$  by Lemma 1.17. Since we assume  $M$  is orientable, the exceptional cases are:

- $N_p = S^1 \times D^2$ . This would have  $T_i$  as its compressible boundary, so this case cannot occur.
- $N_p = S^1 \times S^1 \times I$ . One boundary component of this is  $T_i$ . If the other is a  $T'_i$ , then  $T_i$  and  $T'_i$  would be isotopic, contradicting an earlier assumption. Thus both tori of  $\partial N_p$  come from tori in  $T$ . If these tori in  $T$  are distinct then  $N_p$  gives an isotopy between them so one of them could be omitted from  $T$ , contradicting the minimality of  $T$ . There remains the possibility that both tori of  $\partial N_p$  must come from the same  $T_i$ , but this would mean  $T'$  is empty, a case excluded at the beginning. Thus the case  $N_p = S^1 \times S^1 \times I$  cannot occur.
- $N_p$  is the twisted  $I$ -bundle over a Klein bottle. This has only one boundary component, so  $N_p = M_j \subset M'_j$  and we can change the Seifert-fiberings of  $M_j$  to be the restriction of the Seifert-fiberings of  $M'_j$ .

The same reasoning applies with  $N_q$  and  $M_k$  in place of  $N_p$  and  $M_j$ . The conclusion is that we have Seifert-fiberings of  $M_j$  and  $M_k$  that agree on  $T_i$  since they agree with the fiberings from  $M'_j$ . This means  $T_i$  can be omitted from  $T$ , contrary to minimality, and the proof is complete.  $\square$

## Exercises

1. Show: If  $S \subset M$  is a 1-sided connected surface, then  $\pi_1 S \rightarrow \pi_1 M$  is injective if and only if  $\partial N(S)$  is incompressible, where  $N(S)$  is a twisted  $I$ -bundle neighborhood of  $S$  in  $M$ .
2. Call a 1-sided surface  $S \subset M$  *geometrically incompressible* if for each disk  $D \subset M$

with  $D \cap S = \partial D$  there is a disk  $D' \subset S$  with  $\partial D' = \partial D$ . Show that if  $H_2 M = 0$  but  $H_2(M; \mathbb{Z}_2) \neq 0$  then  $M$  contains a 1-sided geometrically incompressible surface which is nonzero in  $H_2(M; \mathbb{Z}_2)$ . This applies for example if  $M$  is a lens space  $L_{p/2q}$ . Note that if  $q > 1$ , the resulting geometrically incompressible surface  $S \subset L_{p/2q}$  cannot be  $S^2$  or  $\mathbb{R}P^2$ , so the map  $\pi_1 S \rightarrow \pi_1 L_{p/2q}$  is not injective. (See [Frohman] for a study of geometrically incompressible surfaces in Seifert manifolds.)

3.  $S$  is  $\partial$ -incompressible if  $\pi_1(S, \partial S) \rightarrow \pi_1(M, \partial M)$  is injective for all choices of base-point in  $\partial S$ .
4. Develop a canonical torus and Klein bottle decomposition theorem for irreducible nonorientable 3-manifolds.

## Chapter 2. Special Classes of 3-Manifolds

In this chapter we study prime 3-manifolds whose topology is dominated, in one way or another, by embedded tori. This can be regarded as refining the results of the preceding chapter on the canonical torus decomposition

### 1. Seifert Manifolds

Seifert manifolds, introduced in the last chapter where they play a special role in the torus decomposition, are among the best-understood 3-manifolds. In this section our goal is the classification of orientable Seifert manifolds up to diffeomorphism. We begin with the classification up to fiber-preserving diffeomorphism, which is fairly straightforward. Then we show that in most cases the Seifert fibering is unique up to isotopy, so in these cases the diffeomorphism and fiber-preserving diffeomorphism classifications coincide. But there are a few smaller Seifert manifolds, including some with nonunique fiberings, which must be treated by special techniques. Among these are the lens spaces, which we classify later in this section.

The most troublesome Seifert fiberings are those with base surface  $S^2$  and three multiple fibers. These manifolds are too large for the lens space method to work and too small for the techniques of the general case. They have been classified by a study of the algebra of their fundamental groups, but a good geometric classification has yet to be found, so we shall not prove the classification theorem for these Seifert manifolds.

All 3-manifolds in this chapter are assumed to be orientable, compact, and connected. The nonorientable case is similar, but as usual we restrict to orientable manifolds for simplicity.

#### Classification of Seifert Fiberings

We begin with an explicit construction of Seifert fiberings. Let  $B$  be a compact connected surface, not necessarily orientable. Choose disjoint disks  $D_1, \dots, D_k$  in the interior of  $B$ , and let  $B'$  be  $B$  with the interiors of these disks deleted. Let  $M' \rightarrow B'$  be the circle bundle with  $M'$  orientable. Thus if  $B'$  is orientable  $M'$  is the product  $B' \times S^1$ , and if  $B'$  is nonorientable,  $M'$  is the twisted product in which circles in  $B'$  are covered either by tori or Klein bottles in  $M'$  according to whether these circles are orientation-preserving or orientation-reversing in  $B'$ . Explicitly,  $B'$  can be constructed by identifying pairs of disjoint arcs  $a_i$  and  $b_i$  in the boundary of a disk  $D^2$ , and then we can form  $M'$  from  $D^2 \times S^1$  by identifying  $a_i \times S^1$  with  $b_i \times S^1$  via the product of

the given identification of  $a_i$  and  $b_i$  with either the identity or a reflection in the  $S^1$  factor, whichever makes  $M'$  orientable.

Let  $s: B' \rightarrow M'$  be a cross section of  $M' \rightarrow B'$ . For example, we can regard  $M'$  as the double of an  $I$ -bundle, that is, two copies of the  $I$ -bundle with their sub  $\partial I$ -bundles identified by the identity map, and then we can choose a cross section in one of the  $I$ -bundles. The cross section  $s$  together with a choice of orientation for the manifold  $M'$  allows us to speak unambiguously of slopes of nontrivial circles in the tori of  $\partial M'$ . Namely, we can choose a diffeomorphism  $\varphi$  of each component of  $\partial M'$  with  $S^1 \times S^1$  taking the cross section to  $S^1 \times \{y\}$  (slope 0) and a fiber to  $\{x\} \times S^1$  (slope  $\infty$ ). An orientation of  $M'$  induces an orientation of  $\partial M'$ , and this determines  $\varphi$  up to simultaneous reflections of the two  $S^1$  factors, which doesn't affect slopes. We are assuming the standard fact that each nontrivial circle in  $S^1 \times S^1$  is isotopic to a unique 'linear' circle which lifts to the line  $y = (p/q)x$  of slope  $p/q$  in the universal cover  $\mathbb{R}^2$ .

From  $M'$  we construct a manifold  $M$  by attaching  $k$  solid tori  $D^2 \times S^1$  to the torus components  $T_i$  of  $\partial M'$  lying over  $\partial D_i \subset \partial B'$ , attaching by diffeomorphisms taking a meridian circle  $\partial D^2 \times \{y\}$  of  $\partial D^2 \times S^1$  to a circle of some finite slope  $\alpha_i/\beta_i \in \mathbb{Q}$  in  $T_i$ . The  $k$  slopes  $\alpha_i/\beta_i$  determine  $M$  uniquely, since once the meridian disk  $D^2 \times \{y\}$  is attached to  $M'$  there is only one way to fill in a ball to complete the attaching of  $D^2 \times S^1$ . The circle fibering of  $M'$  extends naturally to a Seifert fibering of  $M$  via a model Seifert fibering on each attached  $D^2 \times S^1$ , since the fibers of  $M'$  in  $T_i$  are not isotopic to meridian circles of the attached  $D^2 \times S^1$ . Namely, fibers have slope  $\infty$ , meridians have slope  $\alpha_i/\beta_i \neq \infty$ . Note that the singular fiber in the  $i^{\text{th}}$   $D^2 \times S^1$  has multiplicity  $\beta_i$  since the meridian disk of  $D^2 \times S^1$  is attached to a slope  $\alpha_i/\beta_i$  circle and hence meets each fiber of  $\partial M'$   $\beta_i$  times. Recall that the multiplicity of a singular fiber is the number of times a transverse disk meets nearby regular fibers.

We use the notation  $M(\pm g, b; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$  for this Seifert-fibered manifold  $M$ , where  $g$  is the genus of  $B$ , with the sign  $+$  if  $B$  is orientable and  $-$  if  $B$  is nonorientable, and  $b$  is the number of boundary components of  $B$ . Here 'genus' for nonorientable surfaces means the number of  $\mathbb{R}P^2$  connected summands. Reversing the orientation of  $M(\pm g, b; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$  has the effect of changing it to  $M(\pm g, b; -\alpha_1/\beta_1, \dots, -\alpha_k/\beta_k)$ .

We say two Seifert fiberings are **isomorphic** if there is a diffeomorphism carrying fibers of the first fibering to fibers of the second fibering.

**Proposition 2.1.** (a) Every orientable Seifert-fibered manifold is isomorphic to one of the models  $M(\pm g, b; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$ .

(b) Seifert fiberings  $M(\pm g, b; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$  and  $M(\pm g, b; \alpha'_1/\beta'_1, \dots, \alpha'_k/\beta'_k)$  are isomorphic by an orientation-preserving diffeomorphism if and only if the following two conditions are satisfied:

- (i) After possibly permuting indices,  $\alpha_i/\beta_i \equiv \alpha'_i/\beta'_i \pmod{1}$  for each  $i$ .
- (ii)  $\sum_i \alpha_i/\beta_i = \sum_i \alpha'_i/\beta'_i$  in the special case  $b = 0$ .

This gives the complete isomorphism classification of Seifert fiberings since the numbers  $\pm g$  and  $b$  are determined by the isomorphism class of a fibering, which determines the base surface  $B$ , and the Seifert fiberings  $M(\pm g, b; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$  and  $M(\pm g, b; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k, 0)$  are the same.

**Proof:** Given an oriented Seifert-fibered manifold  $M$ , let  $M'$  be the complement of open solid torus model-fibered neighborhoods of fibers  $C_1, \dots, C_k$  including all multiple fibers. Choose a section  $s$  of the circle bundle  $M' \rightarrow B'$ . As before, this determines slopes for circles in  $\partial M'$ , and we see that  $M$  has the form  $M(\pm g, b; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$ . It remains to see the effect on the  $\alpha_i/\beta_i$ 's of choosing a different section  $s$ .

Let  $a$  be an arc in  $B'$  with endpoints in  $\partial B'$ . Above this in  $M'$  lies an annulus  $A$ . We can rechoose  $s$  near  $A$  so that instead of simply crossing  $A$  transversely, it winds  $m$  times around  $A$  as it crosses. See Figure 2.1. The effect of this change in  $s$  is to add  $m$  to all slopes in the boundary torus of  $M'$  at one edge of  $A$  and subtract  $m$  from all slopes in the boundary torus at the other edge of  $A$ . In particular, if both ends of  $A$  lie in the same boundary torus there is no change in boundary slopes.

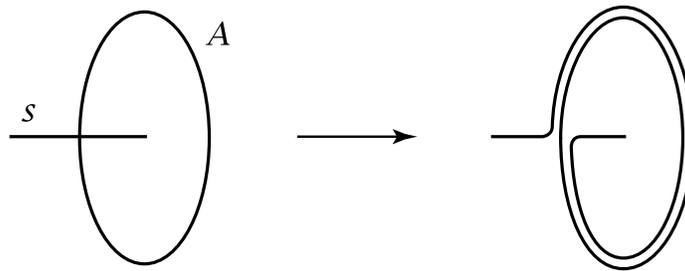

Figure 2.1

Thus if  $b \neq 0$  we can choose  $A$  connecting the boundary torus near the fiber  $C_i$  with a torus in  $\partial M$ , and then change  $\alpha_i/\beta_i$  by any integer, keeping all other  $\alpha_j/\beta_j$ 's fixed. Similarly, if  $b = 0$  we can add and subtract an integer  $m$  from any two  $\alpha_i/\beta_i$ 's, so we can change the  $\alpha_i/\beta_i$ 's to any fractions which are congruent mod 1, subject only to the constraint that  $\sum_i \alpha_i/\beta_i$  stays constant.

We claim that any two choices of the section  $s$  are related by a sequence of 'twist'

modifications near vertical annuli  $A$  as above, together with homotopies through sections, which have no effect on slopes. To see this, take disjoint vertical annuli  $A_j$  splitting  $M'$  into a solid torus. Any two sections can be homotoped, through sections, to coincide outside a neighborhood of the  $A_j$ 's. Then it is clear that near the  $A_j$ 's the two sections can be homotoped to coincide, after inserting the appropriate number of twists.  $\square$

In the case of Seifert fiberings  $M(\pm g, 0; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$  of closed manifolds, the invariant  $\sum_i \alpha_i/\beta_i$  is called the **Euler number** of the fibering. When there are no multiple fibers we can take  $k = 1$  and then the Euler number, which is an integer, is the obstruction to the existence of a section  $B \rightarrow M$ , i.e., the Euler number vanishes if and only if such a section exists. (Exercise.) More generally:

**Proposition 2.2.** *Let  $M$  be an orientable Seifert-fibered manifold.*

- (a) *If  $\partial M \neq \emptyset$ , horizontal surfaces exist in  $M$ .*
- (b) *If  $\partial M = \emptyset$ , horizontal surfaces exist if and only if the Euler number of the fibering is zero.*

**Proof:** In (a), view  $M$  as a circle bundle  $M_0$  with model-fibered solid tori  $M_i$  attached, each  $M_i$  attaching along an annulus in its boundary. Namely, these annuli in  $M$  project to arcs in the base surface cutting off disks each containing the image of one multiple fiber. Given a positive integer  $n$  there is a horizontal surface  $S_0 \subset M_0$  meeting each fiber in  $n$  points. To see this, we can regard  $M_0$  as a quotient of a trivially fibered solid torus  $S^1 \times D^2$  in which certain vertical annuli in  $S^1 \times \partial D^2$  are identified. Each identification can be chosen to be either the identity or a fixed reflection in the  $S^1$  factor. Taking  $n$  points  $x_j \in S^1$  which are invariant (as a set) under the reflection, the  $n$  meridian disks  $\{x_j\} \times D^2$  in  $S^1 \times D^2$  give the desired surface  $S_0$  in the quotient  $M_0$ .

Now let  $n$  be a common multiple of the multiplicities  $q_i$  of the multiple fibers in the solid tori  $M_i$  attached to  $M_0$ . In  $M_i$  let  $S_i$  be the union of  $n/q_i$  meridian disks, so  $S_i$  meets each regular fiber in  $n$  points. We can isotope  $S_i$  through horizontal surfaces so that its  $n$  arcs of intersection with the vertical annulus  $M_0 \cap M_i$  match up with the  $n$  arcs of  $S_0$  in  $M_0 \cap M_i$ . Then the union of  $S_0$  with the  $S_i$ 's is a horizontal surface in  $M$ .

For (b), let  $M = M(\pm g, 0; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$ , with section  $s: B' \rightarrow M'$  as before. Let  $M_0$  be  $M$  with a fibered solid torus neighborhood of a regular fiber in  $M'$  deleted. Suppose  $S_0$  is a horizontal surface in  $M_0$ .

**Claim.** The circles of  $\partial S_0$  in  $\partial M_0$  have slope equal to  $e(M)$ , the Euler number of  $M$ . This easily implies (b): By (a), such a surface  $S_0$  exists. If  $e(M) = 0$ ,  $S_0$  extends via meridian disks in  $M - M_0$  to a horizontal surface  $S \subset M$ . Conversely, if a horizontal surface  $S \subset M$  exists, the surface  $S_0 = S \cap M_0$  must have its boundary circles of slope 0 since these circles bound disks in  $M - M_0$ . So  $e(M) = 0$ .

To prove the Claim, let  $M'_0 = M_0 \cap M'$  and  $S'_0 = S_0 \cap M'$ . The circles of  $\partial S'_0$  in  $\partial M'$  have slopes  $\alpha_i/\beta_i$ , and we must check that the circles of  $\partial S'_0$  in  $\partial M_0$  have slope  $\sum_i \alpha_i/\beta_i$ . This we do by counting intersections of these circles with fibers and with the section  $s$ . Since  $S'_0$  is horizontal, it meets all fibers in the same number of points, say  $n$ . Intersections with  $s$  we count with signs, according to whether the slope of  $\partial S'_0$  near such an intersection point is positive or negative. The total number of intersections of  $\partial S'_0$  with  $s$  is zero because the two intersection points at the end of an arc of  $s \cap S'_0$  have opposite sign. Thus the number of intersections of  $\partial S'_0$  with  $s$  in  $\partial M_0$  equals the number of intersections in  $\partial M'$ . The latter number is  $\sum_i n\alpha_i/\beta_i$  since the slope of  $\partial S'_0$  near the  $i^{\text{th}}$  deleted fiber is  $\alpha_i/\beta_i$ , which must equal the ratio of intersection number with  $s$  to intersection number with fiber; the denominator of this ratio is  $n$ , so the numerator must be  $n\alpha_i/\beta_i$ .

Thus the slope of  $\partial S_0$  is  $(\sum_i n\alpha_i/\beta_i)/n = \sum_i \alpha_i/\beta_i = e(M)$ . □

## Classification of Seifert Manifolds

Here is a statement of the main result:

**Theorem 2.3.** *Seifert fiberings of orientable Seifert manifolds are unique up to isomorphism, with the exception of the following fiberings:*

- (a)  $M(0, 1; \alpha/\beta)$ , the various model Seifert fiberings of  $S^1 \times D^2$ .
- (b)  $M(0, 1; 1/2, 1/2) = M(-1, 1; )$ , two fiberings of  $S^1 \tilde{\times} S^1 \tilde{\times} I$ .
- (c)  $M(0, 0; \alpha_1/\beta_1, \alpha_2/\beta_2)$ , various fiberings of  $S^3$ ,  $S^1 \times S^2$ , and lens spaces.
- (d)  $M(0, 0; 1/2, -1/2, \alpha/\beta) = M(-1, 0; \beta/\alpha)$  for  $\alpha, \beta \neq 0$ .
- (e)  $M(0, 0; 1/2, 1/2, -1/2, -1/2) = M(-2, 0; )$ , two fiberings of  $S^1 \tilde{\times} S^1 \tilde{\times} S^1$ .

The two Seifert fiberings of  $S^1 \tilde{\times} S^1 \tilde{\times} I$  in (b) are easy to see if we view  $S^1 \tilde{\times} S^1 \tilde{\times} I$  as obtained from  $S^1 \times I \times I$  by identifying  $S^1 \times I \times \{0\}$  with  $S^1 \times I \times \{1\}$  via the diffeomorphism  $\varphi$  which reflects both the  $S^1$  and  $I$  factors. One fibering of  $S^1 \tilde{\times} S^1 \tilde{\times} I$  then comes from the fibers  $S^1 \times \{y\} \times \{z\}$  of  $S^1 \times I \times I$  and the other comes from the fibers  $\{x\} \times \{y\} \times I$ ; in the latter case the two fixed points of  $\varphi$  give multiplicity-two fibers.

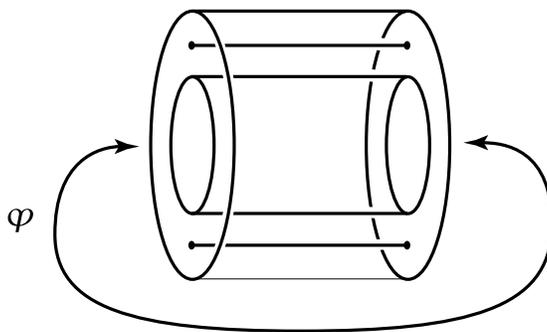

Figure 2.2

Note that the examples in (a) and (b) generate the remaining examples: The fiberings in (c) are obtained by gluing together two model fiberings from (a); (d) is obtained by gluing a model fibering into each of the two fiberings in (b); and (e) is simply the double of (b).

In most cases the Theorem is a consequence of the following:

**Proposition 2.4.** *If  $M_1$  and  $M_2$  are irreducible orientable Seifert-fibered manifolds which are diffeomorphic, then there is a fiber-preserving diffeomorphism provided that  $M_1$  contains vertical incompressible,  $\partial$ -incompressible annuli or tori, and  $M_2$  contains no horizontal incompressible,  $\partial$ -incompressible annuli or tori.*

**Proof:** First we do the case of closed manifolds. In the base surface  $B_1$  of  $M_1$  choose two transversely intersecting systems  $C$  and  $C'$  of disjoint 2-sided circles not passing

through singular points (projections of singular fibers), such that:

- (1) No circle of  $C$  or  $C'$  bounds a disk containing at most one singular point.
- (2) The components of  $B_1 | (C \cup C')$  are disks containing at most one singular point.
- (3) No component of  $B_1 | (C \cup C')$  is a disk bounded by a single arc of  $C$  and a single arc of  $C'$ , and containing no singular point.

For example, one can choose  $C$  to be a single circle, then construct  $C'$  from suitably chosen arcs in  $B_1 | C$ , matching their ends across  $C$ . (Details left as an exercise.) Let  $T$  and  $T'$  be the collections of incompressible vertical tori in  $M_1$  lying over  $C$  and  $C'$ .

Let  $f: M_1 \rightarrow M_2$  be a diffeomorphism. Since  $M_2$  contains no incompressible horizontal tori, we may isotope  $f$  to make  $f(T)$  vertical in  $M_2$  by Proposition 1.12. The circles of  $T \cap T'$  are nontrivial in  $T$ , so we may isotope  $f$  to make the circles of  $f(T \cap T')$  vertical or horizontal in each torus of  $f(T)$ . By condition (3) the annuli of  $T' | (T \cap T')$  are incompressible and  $\partial$ -incompressible in  $M_1 | T$ , so we may isotope  $f$ , staying fixed on  $T$ , to make the annuli of  $f(T') | f(T \cap T')$  vertical or horizontal in  $M_2$ . If any of these were horizontal, they would be part of horizontal tori in  $M_2$ , so we now have  $f(T \cup T')$  vertical in  $M_2$ . Since  $f(T \cap T')$  is vertical, we can isotope  $f$  to be fiber-preserving on  $T \cup T'$ , and then make  $f$  fiber-preserving in a neighborhood  $M'_1$  of  $T \cup T'$ .

By condition (2) the components of  $M_1 - M'_1$  are solid tori, so the same is true for  $M_2 - M'_2$ , where  $M'_2 = f(M'_1)$ . Choose an orientation for  $M_1$  and a section for  $M'_1 \rightarrow B'_1$ . Via  $f$  these choices determine an orientation for  $M_2$  and a section for  $M'_2 \rightarrow B'_2$ . Note that  $f$  induces a diffeomorphism of  $B'_1$  onto  $B'_2$ , so the closed surfaces  $B_1$  and  $B_2$  are diffeomorphic. The fractions  $\alpha_i/\beta_i$  for corresponding solid tori of  $M_1 - M'_1$  and  $M_2 - M'_2$  must be the same since these are the slopes of boundary circles of meridian disks, and  $f$  takes meridian disks to meridian disks (up to isotopy). Thus  $M_1$  and  $M_2$  have the same form  $M(\pm g, 0; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$ , completing the proof for closed manifolds.

For nonempty boundary the proof is similar but easier. Let  $T$  be a collection of incompressible,  $\partial$ -incompressible vertical annuli splitting  $M_1$  into solid tori. Isotope  $f$  first to make  $f(T)$  vertical, then to make  $f$  fiber-preserving in a neighborhood of  $T \cup \partial M_1$ . The rest of the argument now proceeds as in the closed case.  $\square$

Let us see how close Proposition 2.4 comes to proving the Theorem. Consider first the case of irreducible manifolds with nonempty boundary. Then vertical incompressible,  $\partial$ -incompressible annuli exist except in the model fiberings  $M(0, 1; \alpha/\beta)$ . To see when horizontal annuli exist we apply the Euler characteristic formula  $\chi(B) -$

$\chi(S)/n = \sum_i(1 - 1/\beta_i)$ . In the present case  $S$  is an annulus, so we have  $\chi(B) = \sum_i(1 - 1/\beta_i) \geq 0$ , so  $B$  is a disk, annulus, or Möbius band. If  $B = D^2$ , we have  $1 = \sum_i(1 - 1/\beta_i)$ , a sum of terms  $1/2, 2/3, 3/4, \dots$ , so the only possibility is  $1 = 1/2 + 1/2$  and the fibering  $M(0, 1; 1/2, 1/2)$ . If  $B = S^1 \times I$ , we have  $0 = \sum_i(1 - 1/\beta_i)$  so there are no multiple fibers and we have a product fibering  $M(0, 2; )$  of  $S^1 \times S^1 \times I$ . Similarly, if  $B = S^1 \tilde{\times} I$  we have the fibering  $M(-1, 1; )$  of  $S^1 \tilde{\times} S^1 \tilde{\times} I$ . The manifolds  $S^1 \times S^1 \times I$  and  $S^1 \tilde{\times} S^1 \tilde{\times} I$  are not diffeomorphic since they deformation retract onto a torus and a Klein bottle, respectively, and so are of distinct homotopy types. Thus the Theorem follows in the case of irreducible manifolds with nonempty boundary.

For closed irreducible manifolds the analysis is similar but more complicated. Incompressible vertical tori exist unless the base surface  $B$  is  $S^2$  and there are at most three multiple fibers, or  $B$  is  $\mathbb{RP}^2$  and there is at most one multiple fiber. If horizontal tori exist we must have  $\chi(B) \geq 0$ , so there are the following cases:

- $B = S^2$  and  $2 = \sum_i(1 - 1/\beta_i)$ . Since  $1/2 \leq 1 - 1/\beta_i < 1$  there must be either three or four multiple fibers. With four multiple fibers, the multiplicities must all be 2, so we have the fibering  $M(0, 0; 1/2, 1/2, -1/2, -1/2)$  since the Euler number must be zero. With three multiple fibers we have  $1/\beta_1 + 1/\beta_2 + 1/\beta_3 = 1$  so  $(\beta_1, \beta_2, \beta_3) = (2, 3, 6), (2, 4, 4)$ , or  $(3, 3, 3)$ , up to permutations. We leave it for the reader to check that the fibering must be isomorphic to  $M(0, 0; 1/2, -1/3, -1/6)$ ,  $M(0, 0; 1/2, -1/4, -1/4)$ , or  $M(0, 0; 2/3, -1/3, -1/3)$ , allowing orientation-reversing isomorphisms.
- $B = \mathbb{RP}^2$  and  $1 = \sum_i(1 - 1/\beta_i)$ , implying just two multiple fibers, of multiplicity 2. Since the Euler number is zero the fibering must be  $M(-1, 0; 1/2, -1/2)$ .
- $B = S^1 \times S^1$  or  $S^1 \tilde{\times} S^1$  with no multiple fibers and Euler number zero, the fiberings  $M(1, 0; )$  and  $M(-2, 0; )$ .

Thus we have the following six manifolds:

$$\begin{aligned} M_1 &= M(1, 0; ) = S^1 \times S^1 \times S^1 \\ M_2 &= M(-2, 0; ) = M(0, 0; 1/2, 1/2, -1/2, -1/2) = S^1 \tilde{\times} S^1 \tilde{\times} S^1 \\ M_3 &= M(0, 0; 2/3, -1/3, -1/3) \\ M_4 &= M(0, 0; 1/2, -1/4, -1/4) \\ M_5 &= M(0, 0; 1/2, -1/3, -1/6) \\ M_6 &= M(-1, 0; 1/2, -1/2) \end{aligned}$$

Each of these seven fiberings has Euler number zero, hence does in fact contain a horizontal surface  $S$ . By the Euler characteristic formula,  $\chi(S) = 0$ , so  $S$  is either a

torus or Klein bottle. In the latter case  $S$  is one-sided, and the boundary of a tubular neighborhood of  $S$  is a horizontal torus. So horizontal tori exist in all seven Seifert fiberings. As we saw in §1.2 following Proposition 1.12, this implies the manifolds  $M_1$ - $M_6$  are torus bundles or torus semi-bundles.

There remains the case of reducible Seifert manifolds. As shown in the proof of Proposition 1.14 there must exist a horizontal sphere in this case, which implies that the manifold is closed and the Euler number of the Seifert fibering is zero. By the Euler characteristic formula the base surface  $B$  must be  $S^2$  or  $\mathbb{R}P^2$ , with at most three multiple fibers in the first case and at most one multiple fiber in the second case. In the latter case there is in fact no multiple fiber since the Euler number is zero, so we have the Seifert fibering  $M(-1, 0; )$ , and it is not hard to see that this manifold is  $\mathbb{R}P^3 \# \mathbb{R}P^3$ . In the case  $B = S^2$  it is an exercise with fractions to rule out the possibility of three multiple fibers, using the Euler characteristic formula and the fact that the Euler number is zero. Then if there are at most two multiple fibers, we are in the exceptional case (c) of the classification theorem, with a Seifert fibering  $M(0, 0; \alpha/\beta, -\alpha/\beta)$  of  $S^1 \times S^2$ .

To complete the main classification theorem, there remain three things to do:

- (1) Show the manifolds  $M_1$ - $M_6$  above are all distinct, and have only the seven Seifert fiberings listed.
- (2) Classify the Seifert manifolds which possess fiberings over  $S^2$  with at most two multiple fibers.
- (3) Show that the different Seifert fiberings over  $S^2$  with three multiple fibers are all distinct manifolds, distinct also from the manifolds in (2).

We shall do (2) in the following subsection, and in §2.2 we shall do (1) as part of a general classification of torus bundles and torus semi-bundles. As for (3), the only way which seems to be known for doing this is to show these manifolds are all distinguished by their fundamental groups, apart from a few special cases where geometric techniques are available. We shall not cover this in the present version of these notes; see [Orlik] for a proof.

## Classification of Lens Spaces

Let  $L_{p/q}$  be the manifold obtained by attaching two solid tori  $S^1 \times D^2$  together by a diffeomorphism  $\varphi : S^1 \times \partial D^2 \rightarrow S^1 \times \partial D^2$  sending a meridian  $\{x\} \times \partial D^2$  to a circle of slope  $p/q$ , where we use the convention that a meridian has slope  $\infty$  and a longitude  $S^1 \times \{y\}$  has slope 0. The fraction  $p/q$  determines  $L_{p/q}$  completely since circles in

$S^1 \times \partial D^2$  are determined up to isotopy by their slopes, and once the meridian disk of the second  $S^1 \times D^2$  has been attached to the first  $S^1 \times D^2$  there is only one way to attach the remaining 3-ball. Note that  $L_{1/0} = S^1 \times S^2$ , and  $L_{0/1} = S^3$  since  $S^3 = \partial(D^2 \times D^2) = \partial D^2 \times D^2 \cup D^2 \times \partial D^2$ .

The manifolds  $L_{p/q}$  are Seifert-fibered in many ways, by taking model fiberings on the two  $S^1 \times D^2$ 's whose restrictions to  $S^1 \times \partial D^2$  correspond under  $\varphi \in SL_2(\mathbb{Z})$ ; a model fibering on the second  $S^1 \times D^2$  with boundary fibers of slope  $u/v$  extends to a model fibering on the first  $S^1 \times D^2$  provided  $\varphi(u/v) \neq 1/0$ . These Seifert fiberings have base surface  $S^2$  and at most two multiple fibers. Conversely, such a Seifert-fibered manifold is the union of two solid tori with boundaries identified, hence is an  $L_{p/q}$ .

We shall exclude the special case  $L_{1/0} = S^1 \times S^2$  from now on.

The manifold  $L_{p/q}$  can also be obtained as the quotient space  $S^3/\mathbb{Z}_q$  where  $\mathbb{Z}_q$  is the group of rotations of  $S^3$  generated by  $\rho(z_1, z_2) = (e^{2\pi i/q} z_1, e^{2\pi i p/q} z_2)$ , where  $S^3$  is regarded as the unit sphere in  $\mathbb{C}^2$ . This action can be pictured in  $\mathbb{R}^3$ , with the point at infinity added to get  $S^3 = S^1 \times D^2 \cup D^2 \times S^1$ , as a  $1/q$  rotation of the first factor and a  $p/q$  rotation of the second factor.

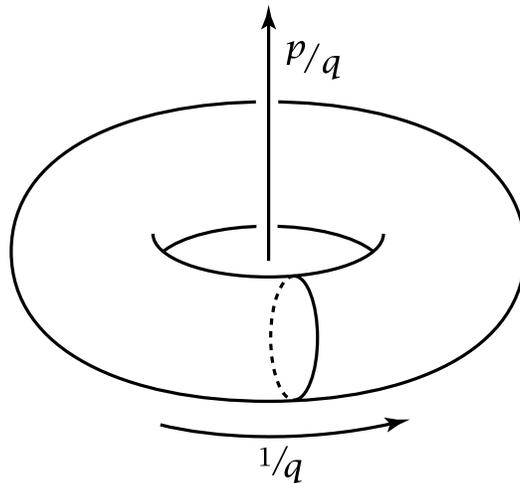

Figure 2.3

Each quotient  $S^1 \times D^2/\mathbb{Z}_q$  and  $D^2 \times S^1/\mathbb{Z}_q$  is a solid torus, so the quotient  $S^3/\mathbb{Z}_q$  has the form  $L_{p'/q'}$ . To see that  $p'/q' = p/q$ , note that slope  $p$  circles on the common boundary torus  $S^1 \times S^1$  are invariant under  $\rho$ , hence become longitudes in  $S^1 \times D^2/\mathbb{Z}_q$ . The boundary circle of a meridian disk of  $D^2 \times S^1/\mathbb{Z}_q$  then intersects the longitude of  $S^1 \times D^2/\mathbb{Z}_q$   $p$  times and the meridian  $q$  times, hence has slope  $p/q$ , up to a sign determined by orientations.

In particular  $\pi_1 L_{p/q} \approx \mathbb{Z}_q$ . This can also be seen directly from the definition of

$L_{p/q}$  since the meridian disk of the second solid torus is attached to  $S^1 \times D^2$  along a circle which wraps around the  $S^1$  factor  $q$  times, and the subsequent attaching of a 3-ball has no effect on  $\pi_1$ . Since  $\pi_1 L_{p/q} \approx \mathbb{Z}_q$ , the number  $q$  is uniquely determined by  $L_{p/q}$ . (We take  $q$  non-negative always.)

For  $p$  there is some ambiguity, however. First, we can rechoose the longitude in  $S^1 \times D^2$  by adding any number of twists around the meridian. This changes slopes by an arbitrary integer, so  $L_{p'/q} = L_{p/q}$  if  $p' \equiv p \pmod{q}$ . Also, reversing the orientation of  $S^1 \times D^2$  changes the sign of slopes, so  $L_{-p/q} = L_{p/q}$ . (We are not specifying an orientation of  $L_{p/q}$ .) Finally, the roles of the two  $S^1 \times D^2$  halves of  $L_{p/q}$  can be reversed, replacing  $\varphi$  by  $\varphi^{-1}$ . Taking  $\varphi = \begin{pmatrix} r & q \\ s & p \end{pmatrix} \in SL_2(\mathbb{Z})$ , then  $\varphi^{-1} = \begin{pmatrix} p & -q \\ -s & r \end{pmatrix}$ , so we obtain  $L_{-r/q} = L_{p/q}$ , where  $r \equiv p^{-1} \pmod{q}$  since  $pr - qs = 1$ . Summarizing,  $L_{p'/q} = L_{p/q}$  if  $p' \equiv \pm p^{\pm 1} \pmod{q}$ .

|| **Theorem 2.5.**  $L_{p'/q}$  is diffeomorphic to  $L_{p/q}$  if and only if  $p' \equiv \pm p^{\pm 1} \pmod{q}$ .

**Proof:** We shall show that there is, up to isotopy, only one torus  $T$  in  $L_{p/q}$  bounding a solid torus on each side. This implies the theorem since such a  $T$  yields a decomposition  $L_{p/q} = S^1 \times D^2 \cup_{\varphi} S^1 \times D^2$ , and the only ambiguities in the slope  $p'/q'$  defining such a representation of  $L_{p/q}$  are the ones considered in the paragraph preceding the theorem: choice of longitude and orientation in the boundary of the first solid torus, and switching the two solid tori.

Let  $T$  be the standard torus bounding solid tori on each side, from the definition of  $L_{p/q}$ . Let  $\Sigma$  be the core circle  $S^1 \times \{0\}$  of the first solid torus  $S^1 \times D^2$  bounded by  $T$ . The union of a meridian disk  $D$  of the second  $S^1 \times D^2$  with the radial segments in slices  $\{x\} \times D^2$  of the first  $S^1 \times D^2$  joining points of  $\partial D$  to  $\Sigma$  is a 2-complex  $\Delta \subset L_{p/q}$ . Abstractly,  $\Delta$  is obtained from the circle  $\Sigma$  by attaching a disk  $D^2$  by a  $q$ -to-1 covering map  $\partial D^2 \rightarrow \Sigma$ .

Let  $T'$  be another torus in  $L_{p/q}$  bounding solid tori on both sides. The concentric copies of  $T'$  in these two solid tori, together with the two core circles, define a singular foliation  $\mathcal{F}$  of  $L_{p/q}$ , whose leaves can also be described as the level sets of a function  $f: L_{p/q} \rightarrow [0, 1]$ .

The first thing we do is put  $\Delta$  in good position with respect to  $\mathcal{F}$ , as follows. Perturb  $\Sigma$  to be disjoint from the two singular leaves (circles) of  $\mathcal{F}$ , and so that  $f|_{\Sigma}$  is a morse function with all critical points in distinct levels. Near local maxima of  $f|_{\Sigma}$ , perturb the  $q$  sheets of  $\Delta$  to lie 'above'  $\Sigma$ , as in Figure 2.4. Likewise, at local minima of  $f|_{\Sigma}$  make  $\Delta$  lie 'below'  $\Sigma$ .

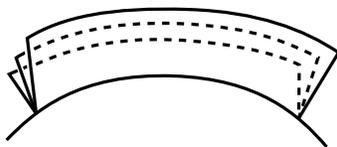

Figure 2.4

Now, keeping  $\Delta$  fixed in a small neighborhood of  $\Sigma$ , perturb  $\Delta$  to be transverse to the two singular leaves of  $\mathcal{F}$  and so that away from these two leaves  $f$  is a morse function on  $\Delta - \Sigma$  with all saddles in levels distinct from each other and from the levels of the critical points of  $f|_{\Sigma}$ .

The foliation  $\mathcal{F}$  then induces a singular foliation on  $\Delta$ , hence also on  $D^2$  via the quotient map  $D^2 \rightarrow \Delta$ . The singularities of the foliation of  $D^2$  are of the following types:

- ‘centers’ in the interior of  $D^2$ , where  $f|_{(\Delta - \Sigma)}$  has local maxima or minima, in particular where  $\Delta$  meets the two singular leaves of  $\mathcal{F}$ .
- saddles in the interior of  $D^2$ .
- ‘half-saddles’ in  $\partial D^2$ , at local maxima or minima of  $f|_{\Sigma}$ .

Figure 2.5 shows the various possible configurations for a singular leaf in  $D^2$  containing a saddle or half-saddle.

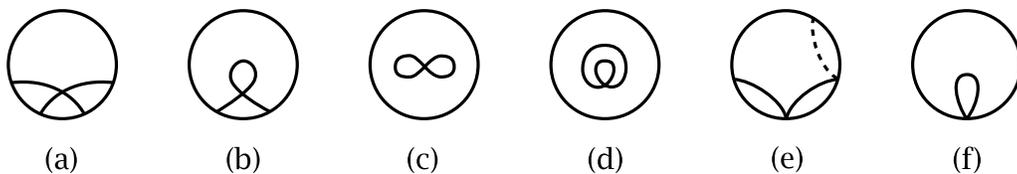

Figure 2.5

Recall that all saddles and half-saddles on  $\Delta$  lie in distinct levels. However, each local maximum or minimum of  $f|_{\Sigma}$  gives  $q$  half-saddles in  $D^2$  in the same level, and some of these may be contained in the same singular leaf, as indicated by the dashed line in case (e). The saddles and half-saddles in cases (a) and (e) are called *essential*, all others *inessential*. In (a) the singular leaf divides  $D^2$  into four *quarter disks*, and in (e) the singular leaf cuts off two or more *half disks* from  $D^2$ .

Let  $D$  be a quarter or half disk containing no other quarter or half disks, and let  $\alpha$  be the arc  $D \cap \partial D^2$ . The two endpoints of  $\alpha$  are part of the same singular leaf, and as we move into the interior of  $\alpha$  we have pairs of points joined by a nonsingular leaf in  $D^2$ . Continuing into the interior of  $\alpha$ , this pairing of points of  $\alpha$  by nonsingular leaves in  $D^2$  continues until we reach an inessential saddle of type (b) or an inessential half-saddle, since  $D$  was chosen as a smallest quarter or half disk, and the singular leaves in cases (c) and (d) do not meet  $\partial D^2$ . An inessential saddle of type (b) presents no

obstacle to continuing the pairing of points of  $\alpha$ , which can therefore continue until we reach an inessential half-saddle. At this point, however, the two paired points of  $\alpha$  coalesce into one point, the half-saddle point itself. We conclude from this that  $D$  contains exactly one inessential half-saddle.

In particular, note that the projection  $\alpha \rightarrow \Sigma$  must be an embedding on the interior of  $\alpha$  since  $f|_{\Sigma}$  has at least two critical points. The two endpoints of  $\alpha$  might have the same image in  $\Sigma$ , however. If this happens,  $D$  must be a half disk and the two endpoints of  $\alpha$  must be half-saddles at the same critical point of  $f|_{\Sigma}$ . In this case isotoping  $\alpha$  rel  $\partial\alpha$  across  $D$  to  $\partial D - \alpha$  induces an isotopy of  $\Sigma$  so that it lies in a leaf of  $\mathcal{F}$ . This is a desirable outcome, as we shall see below, and our next goal is to reduce to this case.

So suppose the disk  $D$  is a half disk and  $\alpha$  has a half-saddle at only one of its endpoints. The configuration is as shown in Figure 2.6. Here we can isotope  $\Sigma$ , and hence  $\Delta$ , via isotopy extension, by dragging  $\alpha$  across  $D$  to a new position, shown in dashed lines, with  $f|_{\Sigma}$  having two fewer critical points.

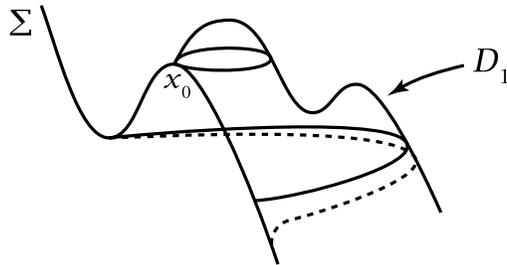

Figure 2.6

The other possibility is that  $D$  is a quarter disk, with the configuration in Figure 2.7 below. In this case we again isotope  $\Sigma$  by pushing  $\alpha$  across  $D$ , dragging the other  $q - 1$  sheets of  $\Delta$  along behind, enlarging them by parallel copies of  $D$ . This does not change the number of critical points of  $f|_{\Sigma}$ , while the number of essential saddles decreases, since the essential saddle in  $\partial D$  becomes  $q$  half-saddles and no new essential saddles are created. (The inessential half-saddle in  $\alpha$  becomes  $q - 1$  inessential saddles. Inessential saddles in the interior of  $D$  are also replicated. In addition, other essential saddles in  $D^2 - D$  may become inessential.)

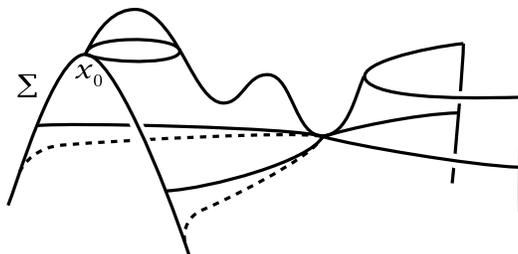

Figure 2.7

Thus after finitely many steps we are reduced to the earlier case when  $\Sigma$  is isotoped into a leaf of  $\mathcal{F}$ , which we may assume is the torus  $T'$ . The circle  $\Sigma$  is nontrivial in  $T'$  since it generates  $\pi_1 L_{p/q} \approx \mathbb{Z}_q$  and we may assume  $q > 1$ . The torus  $T$  is the boundary of a solid torus neighborhood of  $\Sigma$ . Shrinking this neighborhood if necessary, we may assume  $T \cap T'$  consists of two circles, parallel copies of  $\Sigma$  in  $T'$ , so  $T$  intersects each of the solid tori  $X'$  and  $Y'$  bounded by  $T'$  in an annulus, and likewise  $T'$  intersects each of the solid tori  $X$  and  $Y$  bounded by  $T$  in an annulus.

We now appeal to the following fact: An annulus  $A \subset S^1 \times D^2$  with  $\partial A$  consisting of nontrivial, nonmeridional circles in  $S^1 \times \partial D^2$  must be  $\partial$ -parallel. For such an  $A$  must be incompressible since  $\pi_1 A \rightarrow \pi_1(S^1 \times D^2)$  is injective, hence must be either  $\partial$ -incompressible or  $\partial$ -parallel. In the former case  $A$  could be isotoped to be vertical in the product Seifert fibering of  $S^1 \times D^2$ , but then  $A$  would again be  $\partial$ -parallel.

This applies to each of the four annuli of  $T - T'$  and  $T' - T$ . Note that meridional boundary circles cannot occur since  $\Sigma$  is not nullhomotopic in  $L_{p/q}$ . We conclude that the two annuli of  $T - T'$  can be isotoped to the two annuli of  $T' - T$ , as indicated in Figure 2.8, so  $T$  is isotopic to  $T'$ . □

1. What happens if  $\alpha_i/\beta_i = 1/0$  in the manifold  $M(\pm g, b; \alpha_1/\beta_1, \dots, \alpha_k/\beta_k)$ ?

## 2. Torus Bundles and Semi-Bundles

In the preceding section we encountered a few Seifert manifolds which are bundles over the circle with torus fibers. Most torus bundles are not Seifert-fibered, however, though they share one essential feature with most Seifert manifolds: Their topology is dominated by incompressible tori. This makes them easy to classify, and Theorem 2.6 below reduces this classification to understanding conjugacy classes in  $GL_2(\mathbb{Z})$ , an algebraic problem which has a nice geometric solution described later in this section. After the case of torus bundles we move on to a closely-related class of manifolds, torus semi-bundles, which always have a torus bundle as a 2-sheeted covering space.

The torus bundles and torus semi-bundles which are not Seifert-fibered have a special interest because they are the manifolds in one of Thurston's eight geometries, called solvgeometry.

### The Classification of Torus Bundles

A torus bundle has the form of a mapping torus, the quotient  $M_\varphi = T \times I / (x, 0) \sim (\varphi(x), 1)$  for some diffeomorphism  $\varphi \in GL_2(\mathbb{Z})$  of the torus  $T$ . This is because every diffeomorphism  $f: T \rightarrow T$  is isotopic to a linear diffeomorphism  $\varphi \in GL_2(\mathbb{Z})$ . Moreover,  $\varphi$  is uniquely determined by  $f$  since it is essentially the map on  $H_1(T) \approx \mathbb{Z}^2$  induced by  $f$ . By Proposition 1.6,  $M_\varphi$  is irreducible since its universal cover is  $\mathbb{R}^3$ .

Once again we restrict attention to orientable 3-manifolds for simplicity. For  $M_\varphi$  this means restricting  $\varphi$  to be in  $SL_2(\mathbb{Z})$ .

**Theorem 2.6.**  $M_\varphi$  is diffeomorphic to  $M_\psi$  if and only if  $\varphi$  is conjugate to  $\psi^{\pm 1}$  in  $GL_2(\mathbb{Z})$ .

**Proof:** The 'if' half is easy: Applying a diffeomorphism  $f: T \rightarrow T$  in each slice  $T \times \{y\}$  of  $T \times I$  has the effect of conjugating  $\varphi$  by  $f$  when we form the quotient  $M_\varphi = T \times I / (x, 0) \sim (\varphi(x), 1)$ . And by switching the two ends of  $T \times I$  we see that  $M_{\varphi^{-1}}$  is diffeomorphic to  $M_\varphi$ .

The main step in the converse is the following:

**Lemma 2.7.** An incompressible surface in  $M_\varphi$  is isotopic to a union of torus fibers, unless  $\varphi$  is conjugate to  $\pm \begin{pmatrix} 1 & 0 \\ n & 1 \end{pmatrix}$ .

**Proof:** Let  $S \subset M_\varphi$  be incompressible. We may suppose  $S$  has transverse intersection with a fiber  $T_0$  of  $M_\varphi$ . After we eliminate trivial circles of  $S \cap T_0$  by isotopy of  $S$  in the usual way, the surface  $S' = S | T_0$  is incompressible in  $M_\varphi | T_0 = T \times I$ . (Given

a compressing disk  $D$  for  $S'$  in  $T \times I$ , then  $\partial D$  bounds a disk in  $S$ , which must lie in  $S'$  since any intersections with  $T_0$  would be trivial circles of  $S \cap T_0$ .) If  $S'$  is  $\partial$ -compressible, it must have  $\partial$ -parallel annulus components. These can be eliminated by pushing them across  $T_0$ , decreasing the number of circles of  $S \cap T_0$ . So we may assume  $S'$  is incompressible and  $\partial$ -incompressible in  $T \times I$ .

Thinking of  $T \times I$  as a trivial circle bundle,  $S'$  can be isotoped to be either horizontal or vertical, hence to consist either of vertical tori parallel to  $T_0$ , i.e., fibers of  $M_\varphi$ , or annuli whose boundary circles have the same slope in both ends  $T \times \{0\}$  and  $T \times \{1\}$ . In the latter case,  $\varphi$  must preserve this slope in order for  $S'$  to glue together to form the original surface  $S$ . This means  $\varphi$  has an eigenvector in  $\mathbb{Z}^2$ , so is conjugate to  $\pm \begin{pmatrix} 1 & 0 \\ n & 1 \end{pmatrix}$ .  $\square$

Continuing the proof of the theorem, suppose  $f: M_\varphi \rightarrow M_\psi$  is a diffeomorphism. The lemma implies that if  $\psi$  is not conjugate to  $\pm \begin{pmatrix} 1 & 0 \\ n & 1 \end{pmatrix}$ , we can isotope  $f$  to take a fiber  $T$  of  $M_\varphi$  to a fiber of  $M_\psi$ . We may assume that  $T$  is the image of  $T \times \partial I$  in the quotient mapping torus  $T \times I / (x, 0) \sim (\varphi(x), 1)$ , and similarly that  $f(T)$  is the image of  $T \times \partial I$  in  $T \times I / (x, 0) \sim (\psi(x), 1)$ . Then  $f$  is the quotient of a diffeomorphism  $F: T \times I \rightarrow T \times I$ . We may assume  $F$  takes each of  $T \times \{0\}$  and  $T \times \{1\}$  to themselves, rather than interchanging them, by replacing  $\psi$  by  $\psi^{-1}$  if necessary, switching the ends of  $T \times I$ . Let  $f_0$  and  $f_1$  be the restrictions of  $F$  to  $T \times \{0\}$  and  $T \times \{1\}$ . Since  $(x, 0)$  is identified with  $(\varphi(x), 1)$ , it must be that  $(f_0(x), 0)$  is identified with  $(f_1 \varphi(x), 1)$ . But  $(f_0(x), 0)$  is identified with  $(\psi f_0(x), 1)$ , so we conclude that  $f_1 \varphi = \psi f_0$ . This equation implies that  $\varphi$  and  $\psi$  are conjugate in  $GL_2(\mathbb{Z})$  since  $f_0$  and  $f_1$  are isotopic to the same diffeomorphism in  $GL_2(\mathbb{Z})$ , as they induce the same map on  $H_1(T)$ , namely the map induced by  $F$  on  $H_1(T \times I)$ .

There remains the case that  $\psi$  is conjugate, hence we may assume equal, to  $\pm \begin{pmatrix} 1 & 0 \\ n & 1 \end{pmatrix}$ . Since  $\psi$  preserves slope  $\infty$ ,  $M_\psi$  is a circle bundle with fibers the slope  $\infty$  circles in the torus fibers of  $M_\psi$ . It is not hard to see that, with a suitable choice of orientation for  $M_\psi$ , this circle bundle, as a Seifert manifold, is  $M(\varepsilon, 0; n)$  with  $\varepsilon$  equal to either  $+1$  or  $-2$ , the sign of  $\varepsilon$  being the same as the sign of  $\pm \begin{pmatrix} 1 & 0 \\ n & 1 \end{pmatrix}$ . The bundle projection  $M_\psi \rightarrow S^1$  factors as a composition of two circle bundles  $M_\psi \rightarrow B \rightarrow S^1$ , where  $B$  is the base surface of the Seifert fibering.

We may isotope a diffeomorphism  $f: M_\varphi \rightarrow M_\psi$  so that the incompressible torus  $f(T)$ , with  $T$  a fiber of  $M_\varphi$ , is either horizontal or vertical in  $M_\psi$ . If it is vertical, we may rechoose the torus fibering of  $M_\psi$  so that  $f(T)$  is a fiber, by rechoosing the fibering  $B \rightarrow S^1$  so that the image circle of  $f(T)$  is a fiber. (In the case that  $B$  is a Klein

bottle, this circle is 2-sided and nonseparating in  $B$ , so its complement must be an annulus, not a Möbius band.) In the new fibering, the new  $\psi$  is still  $\pm \begin{pmatrix} 1 & 0 \\ n & 1 \end{pmatrix}$  since this matrix was determined by the Seifert fibering  $M(\varepsilon, 0; n)$ , as we saw. Now we have  $f$  taking  $T$  to a torus fiber of  $M_\psi$ , and the argument can be completed as before.

If  $f(T)$  is horizontal we must have the Euler number  $n$  equal to zero, so  $\psi = \pm I$ . We cannot have  $\psi = -I$  since then the base surface of  $M(-2, 0; 0)$  is nonorientable, so the circle fibers of  $M(-2, 0; 0)$  cannot be coherently oriented, which means that the horizontal surface  $f(T)$  is separating, splitting  $M(-2, 0; 0)$  into two twisted  $I$ -bundles. If  $\psi = I$ , then  $M_\psi$  is the 3-torus, and after composing  $f$  with a diffeomorphism in  $GL_3(\mathbb{Z})$  we may assume the map on  $\pi_1$  induced by  $f$  takes the subgroup  $\pi_1 T$  into the  $\mathbb{Z}^2$  subgroup corresponding to the torus fiber of  $M_\psi$ , with cyclic image in  $\pi_1 B$ . Then when we isotope  $f$  to make  $f(T)$  horizontal or vertical,  $f(T)$  cannot be horizontal since for a horizontal surface the projection to  $B$  is a finite-sheeted covering space, with  $\pi_1$ -image of finite index in  $\pi_1 B$ , hence noncyclic. This reduces us to the previous case that  $f(T)$  was vertical.  $\square$

We now determine which Seifert-fibered manifolds are torus bundles  $M_\varphi$ . If the fiber torus  $T$  is isotopic to a vertical surface, then since its complement is  $T \times I$ , which has only the product Seifert fibering, up to isomorphism, the Seifert fibering of  $M_\varphi$  must be of the form  $M(1, 0; n)$  or  $M(-2, 0; n)$ , with  $\varphi$  conjugate to  $\pm \begin{pmatrix} 1 & 0 \\ n & 1 \end{pmatrix}$ . If  $T$  is isotopic to a horizontal surface,  $M_\varphi$  must be one of the manifolds  $M_1$ - $M_5$  from §2.1:

$$\begin{aligned} M_1 &= M(1, 0; ) = S^1 \times S^1 \times S^1, & \text{with } \varphi &= I \\ M_2 &= M(0, 0; 1/2, 1/2, -1/2, -1/2) = S^1 \tilde{\times} S^1 \tilde{\times} S^1, & \text{with } \varphi &= -I \\ M_3 &= M(0, 0; 2/3, -1/3, -1/3), & \text{with } \varphi &= \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix} \\ M_4 &= M(0, 0; 1/2, -1/4, -1/4), & \text{with } \varphi &= \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \\ M_5 &= M(0, 0; 1/2, -1/3, -1/6), & \text{with } \varphi &= \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix} \end{aligned}$$

For  $M_2$  and  $M_4$ ,  $\varphi$  is rotation by 180 and 90 degrees, respectively. For  $M_3$  and  $M_5$ , if we view  $\mathbb{Z}^2$  not as the usual square lattice in  $\mathbb{R}^2$  but as the regular hexagonal lattice,  $\varphi$  is rotation by 120 and 60 degrees, respectively. So for  $M_1$ - $M_5$ ,  $\varphi$  is periodic, of period 1, 2, 3, 4, and 6, respectively. We leave it for the reader to verify that with these  $\varphi$ 's,  $M_\varphi$  is the given Seifert fibering, with circle fibers the images of the segments  $\{x\} \times I \subset T \times I$  in the mapping torus  $M_\varphi$ . This just amounts to checking that the multiple fibers have the multiplicities given, since the Euler number is necessarily zero; see §2.1.

In particular, the theorem implies that none of these Seifert manifolds  $M_1$ - $M_5$  are diffeomorphic to each other or to the manifolds  $M(1,0;n)$  or  $M(-2,0;n)$  with  $n \neq 0$ , since their  $\varphi$ 's are not conjugate, being of different orders. This completes the classification of Seifert-fibered torus bundles, left over from §2.1.

## The Classification of Torus Semi-bundles

Let  $N = S^1 \tilde{\times} S^1 \tilde{\times} I$ , the twisted  $I$ -bundle over the Klein bottle. Two copies of  $N$  glued together by a diffeomorphism  $\varphi$  of the torus  $\partial N$  form a closed orientable manifold  $N_\varphi$ , which we called a torus semi-bundle in §2.1:  $N_\varphi$  is foliated by tori parallel to  $\partial N$ , together with a Klein bottle at the core of each copy of  $N$ . We can identify  $\varphi$ , or rather its isotopy class, with an element of  $GL_2(\mathbb{Z})$  via a choice of coordinates in  $\partial N$ , which we can get by thinking of  $N$  as the quotient of  $S^1 \times S^1 \times I$  obtained by identifying  $(x, y, z)$  with  $(-x, \rho(y), \rho(z))$ , where the  $\rho$ 's are reflections. Then the  $x$  and  $y$  coordinates define 'horizontal' and 'vertical' in  $\partial N$ , and an arbitrary choice of orientations of these directions completes the choice of coordinates for  $\partial N$ .

If we compose  $\varphi$  on the left or the right with a diffeomorphism of  $\partial N$  which extends to a diffeomorphism of  $N$ , then we get the same manifold  $N_\varphi$ . For example, we can compose  $\varphi$  with diffeomorphisms reflecting either the horizontal or vertical directions in  $\partial N$ , with matrices  $\begin{pmatrix} \pm 1 & 0 \\ 0 & \pm 1 \end{pmatrix}$ , since the reflection  $\rho$  acting in either  $S^1$  factor of  $S^1 \times S^1 \times I$  passes down to a diffeomorphism of the quotient  $N$ . As we shall see below, these four diffeomorphisms are, up to isotopy, the only diffeomorphisms of  $\partial N$  which extend over  $N$ .

Replacing  $\varphi$  by  $\varphi^{-1}$  obviously produces the same manifold  $N_\varphi$ , by interchanging the roles of the two copies of  $N$  in  $N_\varphi$ . Thus we have proved the easier 'if' half of the following:

**Theorem 2.8.**  $N_\varphi$  is diffeomorphic to  $N_\psi$  if and only if  $\varphi = \begin{pmatrix} \pm 1 & 0 \\ 0 & \pm 1 \end{pmatrix} \psi^{\pm 1} \begin{pmatrix} \pm 1 & 0 \\ 0 & \pm 1 \end{pmatrix}$  in  $GL_2(\mathbb{Z})$ , with independent choices of signs understood.

**Proof:** First, consider an incompressible,  $\partial$ -incompressible surface  $S \subset N$ . Give  $N$  the Seifert fibering  $M(-1,1;)$  as a circle bundle over the Möbius band, and isotope  $S$  to be either horizontal or vertical. If  $S$  is vertical, it consists either of tori parallel to  $\partial N$ , or nonseparating annuli with boundaries of slope  $\infty$  in  $\partial N$ , with respect to the coordinates in  $\partial N$  chosen earlier. If  $S$  is horizontal it consists of separating annuli with boundaries of slope 0. This can be seen as follows. Orient  $\partial S$  by the positive direction of the  $x$ -coordinate in  $N$ . Let  $s$  be a section of the circle bundle  $N$ , with  $\partial s$  of slope 0. The arcs of  $S \cap s$  pair off the points of  $\partial S \cap \partial s$  into pairs of opposite

sign, so  $S$  and  $s$  have algebraic intersection number 0. Since all the components of  $\partial S$  have parallel orientations, each component must have intersection number 0 with  $\partial s$ , hence must have slope 0.

Now let  $S$  be an incompressible surface in  $N_\psi$ . As in the proof of Lemma 2.7, we may isotope  $S$  so that for each of the two copies  $N_1$  and  $N_2$  of  $N$  whose union is  $N_\psi$ ,  $S \cap N_i$  is an incompressible,  $\partial$ -incompressible surface  $S_i$  in  $N_i$ . By the preceding paragraph, either  $S$  consists of parallel copies of the torus  $T$  splitting  $N_\psi$  into  $N_1$  and  $N_2$ , or  $\psi$  takes slope 0 or  $\infty$  to slope 0 or  $\infty$ . We shall see later that this means  $N_\psi$  is Seifert-fibered.

Suppose  $f: N_\varphi \rightarrow N_\psi$  is a diffeomorphism, and let  $T$  be the torus in  $N_\varphi$  splitting  $N_\varphi$  into two copies of  $N$ . Applying the preceding remarks to  $S = f(T)$ , there are two possibilities:

(1) We can isotope  $f$  so that  $f(T)$  is the torus splitting  $N_\psi$  into two copies of  $N$ . Then  $\varphi$  must be obtained from  $\psi$  by composing on the left and right by diffeomorphisms of  $\partial N$  which extend to diffeomorphisms of  $N$ . Such diffeomorphisms must preserve slope 0 and slope  $\infty$ , since these are the unique slopes of the boundaries of incompressible,  $\partial$ -incompressible separating and nonseparating annuli in  $N$ , respectively, as noted earlier. The theorem is thus proved in this case.

(2) We can isotope  $f$  so that  $f(T)$  meets each of the two copies of  $N$  in incompressible,  $\partial$ -incompressible annuli. These must be separating, since  $T$  is separating, so they must have boundaries of slope 0. Thus  $\psi$  preserves slope 0, having, we may assume, the form  $\begin{pmatrix} 1 & n \\ 0 & 1 \end{pmatrix}$ . In this case if we take all the slope 0 circles in the torus and Klein bottle fibers of the torus semi-bundle  $N_\psi$  we obtain the Seifert fibering  $M(0, 0; 1/2, 1/2, -1/2, -1/2, n)$ , with Euler number  $n$ , as the reader can verify by inspection. The torus  $f(T)$  can be isotoped to be vertical in this Seifert fibering, since horizontal surfaces in  $M(0, 0; 1/2, 1/2, -1/2, -1/2, n)$  are nonseparating (because the base surface of this Seifert fibering is orientable, hence the fiber circles are coherently orientable, making any horizontal surface the fiber of a surface bundle). We can then rechoose the torus semi-bundle structure on  $N_\psi$  so that  $f(T)$  becomes a fiber torus. (The other torus and Klein bottle fibers are also unions of circle fibers of  $M(0, 0; 1/2, 1/2, -1/2, -1/2, n)$ .) The  $\psi$  for the new torus semi-bundle structure is clearly the same as the old one, namely  $\begin{pmatrix} 1 & n \\ 0 & 1 \end{pmatrix}$ . So this reduces us to case (1).  $\square$

Which Seifert fiberings are torus semi-bundles  $N_\varphi$ ? If the torus fiber is vertical in the Seifert fibering, it splits  $N_\varphi$  into two Seifert-fibered copies of  $N$ . Since  $N$  has just the two Seifert fiberings  $M(-1, 1; )$  and  $M(0, 1; 1/2, 1/2)$ , the possibilities are:

- (1)  $M(-2, 0; n)$ , with  $\varphi = \begin{pmatrix} 1 & 0 \\ n & 1 \end{pmatrix}$
- (2)  $M(-1, 0; 1/2, -1/2, n)$ , with  $\varphi = \begin{pmatrix} 0 & 1 \\ 1 & n \end{pmatrix}$ , or equivalently  $\begin{pmatrix} n & 1 \\ 1 & 0 \end{pmatrix}$
- (3)  $M(0, 0; 1/2, 1/2, -1/2, -1/2, n)$ , with  $\varphi = \begin{pmatrix} 1 & n \\ 0 & 1 \end{pmatrix}$

On the other hand, if the torus fiber of  $N_\varphi$  is horizontal, then as we saw in §2.1, the Seifert fibering is either the one in (1) or (2) with  $n = 0$ .

The theorem implies that all the manifolds listed in (1)-(3) are distinct, modulo changing the sign of  $n$  and the coincidence of (1) and (3) when  $n = 0$ . In most cases this was already proved in §2.1. The one exception is the manifold  $M(-1, 0; 1/2, -1/2)$ , labelled  $M_6$  in §2.1, which we did not then distinguish from the other manifolds in (1)-(3).

For each  $N_\varphi$  there is a torus bundle  $M_\psi$  which is a natural 2-sheeted covering space of  $N_\varphi$ . Over each of the two copies of  $N$  in  $N_\varphi$ ,  $M_\psi$  consists of the double cover  $S^1 \times S^1 \times I \rightarrow N$  by which  $N$  was defined. The first copy of  $S^1 \times S^1 \times I$  is glued to the second by  $\varphi$  along  $S^1 \times S^1 \times \{0\}$  and by  $\tau\varphi\tau$  along  $S^1 \times S^1 \times \{1\}$ , where  $\tau(x, y) = (-x, \rho(y))$ , as in the definition of  $N$ . Thus  $\psi = \tau\varphi^{-1}\tau\varphi$ . Since the 2-sheeted covering  $M_\psi \rightarrow N_\varphi$  takes fibers to fibers, it fits into a commutative diagram as at the right, where the two vertical maps are the bundle and semi-bundle projections, and the map  $S^1 \rightarrow I$  is the ‘folding’ map

$$\begin{array}{ccc} M_\psi & \longrightarrow & N_\varphi \\ \downarrow & & \downarrow \\ S^1 & \longrightarrow & I \end{array}$$

which factors out by the reflection  $\rho$ . The bundle  $M_\psi \rightarrow S^1$  can be regarded as the pullback of the semi-bundle  $N_\varphi \rightarrow I$  via the folding map  $S^1 \rightarrow I$ . There are similar  $n$ -to-1 folding maps  $I \rightarrow I$ , folding up  $I$  like an  $n$ -segmented carpenter’s ruler, and  $N_\varphi \rightarrow I$  can be pulled back to other torus semi-bundles via these folding maps.

## The Geometry of $SL(2, \mathbb{Z})$

A matrix  $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL_2(\mathbb{Z})$  gives rise to a linear fractional transformation  $z \mapsto (az + b)/(cz + d)$  of the Riemann sphere  $\mathbb{C} \cup \{\infty\}$ . Since this has real coefficients it takes  $\mathbb{R} \cup \{\infty\}$  to itself, preserving orientation since the determinant is positive. Hence it takes the upper half plane to itself since all linear fractional transformations preserve orientation of  $\mathbb{C} \cup \{\infty\}$ . Let  $\mathcal{H}$  denote the upper half plane, including its boundary points  $\mathbb{R} \cup \{\infty\}$ . The action of  $SL_2(\mathbb{Z})$  on  $\mathcal{H}$  extends to an action of  $GL_2(\mathbb{Z})$  on  $\mathcal{H}$  if we identify points in the upper and lower half planes via complex conjugation, since a linear fractional transformation with real coefficients takes conjugate points to conjugate points. Then an element of  $GL_2(\mathbb{Z})$  preserves or reverses orientation of  $\mathcal{H}$  according to whether its determinant is  $+1$  or  $-1$ .

For a matrix  $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in GL_2(\mathbb{Z})$  let  $\ell_A$  be the semicircle in  $\mathcal{H}$  orthogonal to  $\partial\mathcal{H}$

with endpoints at the rational numbers  $c/a$  and  $d/b$  in  $\partial\mathcal{H}$ . We orient  $\ell_A$  from  $c/a$  to  $d/b$ . In case  $a$  or  $b$  is zero,  $\ell_A$  is a vertical line in  $\mathcal{H}$  with lower endpoint at  $d/b$  or  $c/a$ , respectively, and other ‘endpoint’ at  $\infty = \pm 1/0$ . Note that there are exactly four  $A$ ’s with the same oriented  $\ell_A$ , obtained by multiplying either column of  $A$  by  $-1$ . When the interior of  $\mathcal{H}$  is taken as a model for the hyperbolic plane, the  $\ell_A$ ’s are geodesics, so we shall refer to them as ‘lines.’

The collection of all the lines  $\ell_A$  is invariant under the action of  $GL_2(\mathbb{Z})$  on  $\mathcal{H}$ . Namely, if  $A, B \in GL_2(\mathbb{Z})$  then  $A(\ell_B) = \ell_{AB}$ , as the reader can readily verify using the fact that linear fractional transformations preserve angles and take circles and lines in  $\mathbb{C}$  to circles or lines. Note that this action is transitive:  $\ell_B = BA^{-1}(\ell_A)$ .

**Proposition 2.9.** *The collection of all lines  $\ell_A$  forms a tessellation  $\mathcal{T}$  of  $\mathcal{H}$  by ideal triangles: triangles with their vertices on  $\partial\mathcal{H}$ .*

See Figure 2.9 for two pictures of this tessellation  $\mathcal{T}$ , the second picture being a redrawing of the first to make  $\mathcal{H}$  a disk.

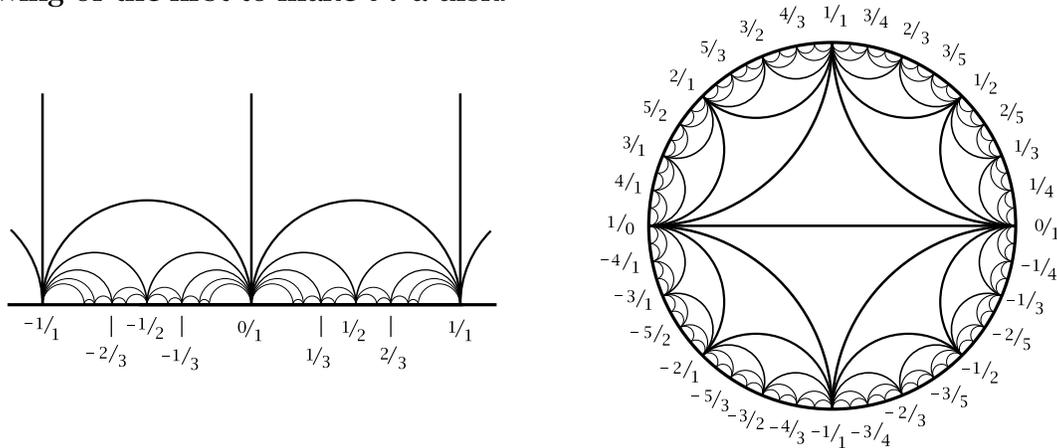

Figure 2.9

**Proof:** First we check that no two lines  $\ell_A$  cross. Since the action of  $GL_2(\mathbb{Z})$  on the  $\ell_A$ ’s is transitive, it suffices to consider an  $\ell_A$  crossing  $\ell_I$ . If  $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$  and  $\ell_A$  is oriented from left to right (which can be achieved by switching the columns of  $A$  if necessary), then  $c/a < 0 < d/b$ . We may assume  $c$  is negative and  $a, b$ , and  $d$  are positive. But then  $ad - bc > 1$ , which is impossible since elements of  $GL_2(\mathbb{Z})$  have determinant  $\pm 1$ .

Next we observe that any two rational numbers are joined by an edgepath consisting of finitely many edges  $\ell_A$ , each two successive edges in the edgepath having a common vertex. For given  $c/a \in \mathbb{Q}$  with  $(a, c) = 1$ , there exist integers  $b, d$  with  $ad - bc = \pm 1$ , so  $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in GL_2(\mathbb{Z})$ . Thus each rational is the endpoint of a line  $\ell_A$ . To

get an edgepath joining  $c/a$  to  $0/1$ , use the fact that  $\begin{pmatrix} a & b \\ c & d \end{pmatrix}$  can be reduced to a diagonal matrix by a sequence of elementary column operations, each operation consisting of adding an integer multiple of one column to the other column. (This is essentially the Euclidean algorithm in  $\mathbb{Z}$ .) This produces a finite sequence of matrices in  $GL_2(\mathbb{Z})$ , each pair of successive matrices having a column in common, so the corresponding sequence of  $\ell_A$ 's forms an edgepath. The final edge has endpoints  $0 = 0/\pm 1$  and  $\infty = \pm 1/0$ , since the diagonal matrix has  $\pm 1$ 's down the diagonal.

The three  $\ell_A$ 's with endpoints  $0/1$ ,  $1/0$ , and  $1/1$  form one triangle in  $\mathcal{H}$ . Let  $U$  be the union of all the images of this triangle under the action of  $GL_2(\mathbb{Z})$ , with all vertices in  $\partial\mathcal{H}$  deleted. To finish the proof we need to show that  $U = \text{int}(\mathcal{H})$ . We do this by showing that  $U$  is both open and closed in  $\text{int}(\mathcal{H})$ . Openness is clear, since  $GL_2(\mathbb{Z})$  acts transitively on the  $\ell_A$ 's, and the edge  $\ell_I$  is shared by the two triangles whose third vertices are  $+1$  and  $-1$ . If  $U$  were not closed, there would be an infinite sequence  $z_i \in U$  converging to a point  $z \in \text{int}(\mathcal{H}) - U$ . We may assume the  $z_i$ 's lie in distinct lines  $\ell_{A_i}$ . Since no  $\ell_{A_i}$ 's cross, there would have to be a limit line  $\ell$  containing  $z$ . Since  $z \notin U$ ,  $\ell$  is not an  $\ell_A$ . Neither endpoint of  $\ell$  can be rational since every line through a rational point crosses lines  $\ell_A$  (true for  $1/0$ , hence true for all rationals by transitivity) and if  $\ell$  crossed an  $\ell_A$  so would some  $\ell_{A_i}$ . On the other hand, if both endpoints of  $\ell$  are irrational, then again  $\ell$  cannot cross any  $\ell_A$ 's, and in this case it would not be possible to join rationals on one side of  $\ell$  to rationals on the other side by edgepaths consisting of  $\ell_A$ 's, contradicting an earlier observation. Thus  $U$  must be closed in  $\text{int}(\mathcal{H})$ .  $\square$

For the action of  $GL_2(\mathbb{Z})$  on  $\mathcal{H}$ , only  $\pm I$  act as the identity. So we have an injection of the quotient  $PGL_2(\mathbb{Z}) = GL_2(\mathbb{Z})/\pm I$  into the symmetry group of the tessellation  $\mathcal{T}$ . This is in fact an isomorphism, since  $PGL_2(\mathbb{Z})$  acts transitively on oriented edges, and also contains orientation-reversing maps of  $\mathcal{H}$ . The index-two subgroup  $PSL_2(\mathbb{Z})$  is the group of orientation-preserving symmetries of  $\mathcal{T}$ .

An element  $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL_2(\mathbb{Z})$  not equal to  $\pm I$  has one or two fixed points in  $\mathcal{H}$ , the roots of the quadratic  $z = (az + b)/(cz + d)$ . There are three possibilities:

(1) There are two distinct real irrational roots  $r_1$  and  $r_2$ . Then the line (semicircle) in  $\mathcal{H}$  joining  $r_1$  and  $r_2$  is invariant under  $A$ . The infinite sequence of triangles of  $\mathcal{T}$  meeting this line is arranged in a periodic pattern, invariant under  $A$ , which acts as a translation of this strip, as in Figure 2.10, with  $a_i$  triangles having a common vertex on one side of the strip, followed by  $a_{i+1}$  triangles with a common vertex on the other side, etc.

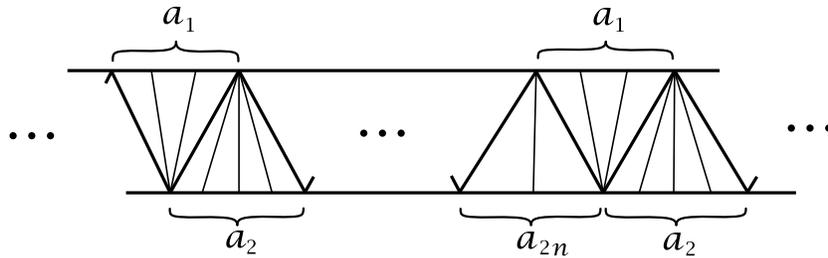

Figure 2.10

The cycle  $(a_1, \dots, a_{2n})$  is a complete invariant of the conjugacy class of  $A$  in  $PGL_2(\mathbb{Z})$ , by our earlier comment that  $PGL_2(\mathbb{Z})$  is the full symmetry group of  $\mathcal{T}$ . The fixed points  $r_1$  and  $r_2$  are slopes of eigenvectors of  $A$ . The two corresponding eigenvalues have the same sign since  $A \in SL_2(\mathbb{Z})$ , and this sign together with the cycle  $(a_1, \dots, a_{2n})$  is a complete invariant of the conjugacy class of  $A$  in  $GL_2(\mathbb{Z})$ . A specific representative of this conjugacy class is

$$\pm \begin{pmatrix} 1 & 0 \\ a_1 & 1 \end{pmatrix} \begin{pmatrix} 1 & a_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ a_3 & 1 \end{pmatrix} \cdots \begin{pmatrix} 1 & a_{2n} \\ 0 & 1 \end{pmatrix}$$

The conjugacy class of  $A^{-1}$  is represented by the inverse cycle  $(a_{2n}, \dots, a_1)$  with the same sign of the eigenvalues. Geometrically, we can think of the conjugacy class of the pair  $\{A, A^{-1}\}$  as the triangulated cylinder obtained from the strip in Figure 5.2 by factoring out by the translation  $A$ , together with a sign. Diffeomorphism classes of torus bundles  $M_\varphi$  with  $\varphi$  having distinct real eigenvalues correspond bijectively with such triangulated, signed cylinders, by Theorem 2.6.

(2) There is only one rational root  $r$ . In this case the triangles having  $r$  as a vertex form a degenerate infinite strip, with quotient a cone divided into some number  $n$  of triangles. The number  $n$  together with the sign of the eigenvalue  $\pm 1$  of  $A$  is a complete invariant of the conjugacy class of  $\{A, A^{-1}\}$  in  $GL_2(\mathbb{Z})$ . A representative of this conjugacy class is  $\pm \begin{pmatrix} 1 & n \\ 0 & 1 \end{pmatrix}$ .

(3) There are two complex conjugate roots. The root in  $\text{int}(\mathcal{H})$  gives a fixed point of  $A$  in  $\text{int}(\mathcal{H})$ , so  $A$  acts either by rotating a triangle 120 degrees about its center or by rotating an edge 180 degrees about its center. Since  $PGL_2(\mathbb{Z})$  acts transitively on triangles and edges, these rotations of  $\mathcal{H}$  fall into two conjugacy classes in  $PGL_2(\mathbb{Z})$ , according to the angle of rotation. In  $GL_2(\mathbb{Z})$  we thus have just the conjugacy classes of the matrices of orders 2, 3, 4, and 6 discussed earlier.

Now let us use the tessellation  $\mathcal{T}$  to make explicit the equivalence relation on elements of  $GL_2(\mathbb{Z})$  corresponding to diffeomorphism of torus semi-bundles, described

in Theorem 2.8. An element  $A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in GL_2(\mathbb{Z})$  determines an oriented edge  $\ell_A$  in  $\mathcal{T}$ , as above. The other three  $A$ 's with the same oriented  $\ell_A$  differ by multiplication on the right by  $\begin{pmatrix} \pm 1 & 0 \\ 0 & \pm 1 \end{pmatrix}$ , so give the same torus semi-bundle  $N_A$ . Multiplication on the left by  $\begin{pmatrix} \pm 1 & 0 \\ 0 & \pm 1 \end{pmatrix}$  corresponds either to the identity of  $\mathcal{H}$  or a reflection of  $\mathcal{H}$  across the edge  $\ell_I$ , so we may normalize  $A$  by choosing it so that  $\ell_A$  lies in the right half of  $\mathcal{H}$ . Let  $T(A)$  be the smallest connected union of triangles of  $\mathcal{T}$  containing  $\ell_I$  and  $\ell_A$ . This is a finite triangulated strip with two distinguished oriented edges in its boundary,  $\ell_I$  and  $\ell_A$ , as in Figure 2.11.

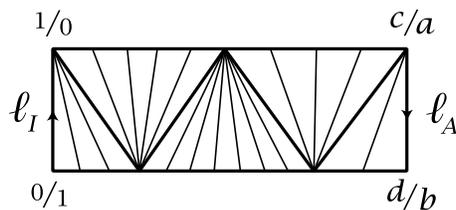

Figure 2.11

In degenerate cases the top or bottom edges of the strip can reduce to a single point. We leave it as an exercise for the reader to check that  $T(A^{-1})$  is obtained from  $T(A)$  by simply interchanging the labelling of the two oriented edges  $\ell_I$  and  $\ell_A$ . Thus diffeomorphism classes of torus semi-bundles correspond bijectively with isomorphism classes of triangulated strips with oriented left and right edges.

As another exercise, the reader can show that the torus bundle double covering  $N_A$ , as described earlier in this section, corresponds to the cylinder (or cone) obtained by gluing two copies of  $T(A)$  together by the identity map of their boundary, with the sign  $+1$  if the two ends of  $T(A)$  have parallel orientation and the sign  $-1$  in the opposite case; this assumes we are not in the degenerate case that  $T(A)$  is just a single edge, with no triangles.

# Chapter 3. Homotopy Properties

## 1. The Loop and Sphere Theorems

These are the basic results relating homotopy theory, specifically  $\pi_1$  and  $\pi_2$ , to more geometric properties of 3-manifolds.

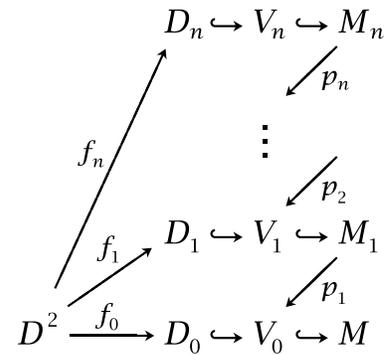

### The Loop Theorem

Let  $M$  be a 3-manifold-with-boundary, not necessarily compact or orientable.

**Theorem 3.1.** *If there is a map  $f : (D^2, \partial D^2) \rightarrow (M, \partial M)$  with  $f|_{\partial D^2}$  not nullhomotopic in  $\partial M$ , then there is an embedding with the same property.*

**Proof:** The first half of the proof consists of covering space arguments which reduce the problem to finitely many applications of the relatively simple special case that  $f$  is at most two-to-one. The second half of the proof then takes care of this special case. It is a curious feature of the proof that at the end of the first step one discards the original  $f$  completely and starts afresh with a new and nicer  $f$ .

It seems more convenient to carry out the first half of the proof in the piecewise linear category. Choose a triangulation of  $M$  and apply the simplicial approximation theorem (for maps of pairs) to homotope the given  $f$  to a map  $f_0$  which is simplicial in some triangulation of the domain  $D^2$  and which still satisfies the same hypotheses as  $f$ . We now construct a diagram as at the right. To obtain the bottom row, let  $D_0$  be  $f_0(D^2)$ , a finite subcomplex of  $M$ , and let  $V_0$  be a neighborhood of  $D_0$  in  $M$  that is a compact 3-manifold deformation retracting onto  $D_0$ . The classical construction of such a  $V_0$  is to take the union of all simplices in the second barycentric subdivision of  $M$  that meet  $D_0$ .

In particular,  $V_0$  is connected since  $D_0$  is connected. If  $V_0$  has a connected 2-sheeted cover  $p_1 : M_1 \rightarrow V_0$ , then  $f_0$  lifts to a map  $f_1 : D^2 \rightarrow M_1$  since  $D^2$  is simply-connected. Let  $D_1 = f_1(D^2)$  and let  $V_1$  be a neighborhood of  $D_1$  in  $M_1$  chosen as before. This gives the second row of the diagram. If  $V_1$  has a connected 2-sheeted cover we can repeat the process to construct a third row, and so on up the tower.

To see that we must eventually reach a stage where the tower cannot be continued further, consider the covering  $p_i^{-1}(D_{i-1}) \rightarrow D_{i-1}$ . Both these spaces have natural simplicial structures with simplices lifting the simplices of  $D_0$ . The nontrivial deck transformation  $\tau_i$  of the covering space  $p_i^{-1}(D_{i-1}) \rightarrow D_{i-1}$  is a simplicial homeomorphism.

Since  $M_i$  is connected, so is  $p_i^{-1}(D_{i-1})$  since  $M_i$  deformation retracts to  $p_i^{-1}(D_{i-1})$  by lifting a deformation retraction of  $V_{i-1}$  to  $D_{i-1}$ . The set  $p_i^{-1}(D_{i-1}) = D_i \cup \tau_i(D_i)$  is connected, so  $D_i \cap \tau_i(D_i)$  must be nonempty. This means that  $\tau_i$  must take some simplex of  $D_i$  to another simplex of  $D_i$ , distinct from the first simplex since  $\tau_i$  has no fixed points. These two simplices of  $D_i$  are then identified in  $D_{i-1}$ , so  $D_{i-1}$  is a quotient of  $D_i$  with fewer simplices than  $D_i$ . Since the number of simplices of  $D_i$  is bounded by the number of simplices in the original triangulation of the source  $D^2$ , it follows that the height of the tower is bounded.

Thus we arrive at a  $V_n$  having no connected 2-sheeted cover. This says that  $\pi_1 V_n$  has no subgroup of index two, so there is no nontrivial homomorphism  $\pi_1 V_n \rightarrow \mathbb{Z}_2$ , and hence  $H^1(V_n; \mathbb{Z}_2) = \text{Hom}(H_1(V_n), \mathbb{Z}_2) = 0$ . In the exact sequence

$$H_2(V_n, \partial V_n; \mathbb{Z}_2) \rightarrow H_1(\partial V_n; \mathbb{Z}_2) \rightarrow H_1(V_n; \mathbb{Z}_2)$$

the first term is zero since it is isomorphic to  $H^1(V_n; \mathbb{Z}_2)$  by Poincaré duality, and the third term is zero since it is isomorphic to  $H^1(V_n; \mathbb{Z}_2)$  by the universal coefficient theorem. Exactness then implies that the middle term  $H_1(\partial V_n; \mathbb{Z}_2)$  is zero, which means that all the components of the compact surface  $\partial V_n$  are 2-spheres.

In the component of  $\partial V_i$  containing  $f_i(\partial D^2)$ , let  $F_i = (p_1 \circ \cdots \circ p_i)^{-1}(\partial M)$ . This will be a compact surface if the neighborhoods  $V_i$  are chosen with sufficient care. Let  $N_i \subset \pi_1 F_i$  be the kernel of  $(p_1 \circ \cdots \circ p_i)_* : \pi_1 F_i \rightarrow \pi_1(\partial M)$ . Note that  $[f_i | \partial D^2] \notin N_i$  by the initial hypothesis on  $f$ , so  $N_i$  is a proper normal subgroup of  $\pi_1 F_i$ .

At the top of the tower the surface  $F_n$  is a planar surface, being a subsurface of a sphere. Hence  $\pi_1 F_n$  is normally generated by the circles of  $\partial F_n$ . Since  $N_n \neq \pi_1 F_n$ , some circle of  $\partial F_n$  must represent an element of  $\pi_1 F_n - N_n$ . This circle bounds a disk in  $\partial V_n$ . Let  $g_n : D^2 \rightarrow V_n$  be this embedding of a disk, with its interior pushed into  $V_n$  so as to be a proper embedding. We have  $[g_n | \partial D^2] \notin N_n$ . We can take  $g_n$  to be a smooth embedding and work from now on in the smooth category.

The rest of the proof consists of descending the tower step by step, producing embeddings  $g_i : D^2 \rightarrow V_i$  with  $[g_i | \partial D^2] \notin N_i$ . In the end we will have an embedding  $g_0 : D^2 \rightarrow V_0 \subset M$  with  $[g_0 | \partial D^2] \notin N_0$ , which says that  $g_0 | \partial D^2$  is not nullhomotopic in  $\partial M$ , and the proof will be complete.

Consider the inductive step of producing  $g_{i-1}$  from  $g_i$ . Since  $p_i$  is a 2-sheeted cover, we can perturb  $g_i$  so that the immersion  $p_i g_i$  has only simple double curves, either circles or arcs, where two sheets of  $p_i g_i(D^2)$  cross transversely. Our aim is to modify  $g_i$  so as to eliminate each of these double curves in turn.

Suppose  $C$  is a double circle. A neighborhood  $N(C)$  of  $C$  in  $p_i g_i(D^2)$  is a bundle

over  $C$  with fiber the letter  $X$ . Thus  $N(C)$  is obtained from  $X \times [0, 1]$  by identifying  $X \times \{0\}$  with  $X \times \{1\}$  by some homeomorphism given by a symmetry of  $X$ . A 90 degree rotational symmetry is impossible since  $p_i$  is two-to-one. A 180 degree rotational symmetry is also impossible since it would force the domain  $D^2$  to contain a Möbius band. For the same reason a symmetry which reflects the  $X$  across one of its crossbars is impossible. The two remaining possibilities are the identity symmetry, with  $N(C) = X \times S^1$ , and a reflection of  $X$  across a horizontal or vertical line. Note that a reflection can occur only if  $M$  is nonorientable.

In the case that  $N(C) = X \times S^1$  there are two circles in  $D^2$  mapping to  $C$ . These circles bound disks  $D_1$  and  $D_2$  in  $D^2$ . If  $D_1$  and  $D_2$  are nested, say  $D_1 \subset D_2$ , then we redefine  $g_i$  on  $D_2$  to be  $g_i|_{D_1}$ , smoothing the resulting corner along  $C$ . This has the effect of eliminating  $C$  from the self-intersections of  $p_i g_i(D^2)$ , along with any self-intersections of the immersed annulus  $p_i g_i(D_2 - D_1)$ . If  $D_1$  and  $D_2$  are disjoint we modify  $g_i$  by interchanging its values on the disks  $D_1$  and  $D_2$ , then smoothing the resulting corners along  $C$ , as shown in Figure 3.1(a). Thus we eliminate the circle  $C$  from the self-intersections of  $p_i g_i(D^2)$  without introducing any new self-intersections.

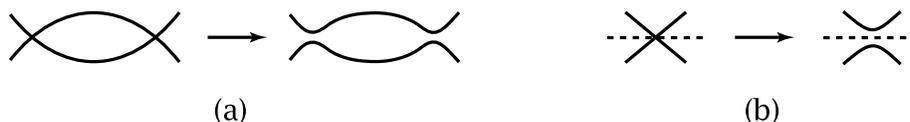

Figure 3.1

In the opposite case that  $N(C)$  is not  $X \times S^1$  we modify the immersed disk  $p_i g_i(D^2)$  in the way shown in Figure 3.1(b), replacing each cross-sectional  $X$  of  $N(C)$  by two disjoint arcs. This replaces an immersed annulus by an embedded annulus with the same boundary, so the result is again an immersed disk with fewer double circles. Iterating these steps, all double circles can be eliminated without changing  $g_i|_{\partial D^2}$ .

Now consider the case of a double arc  $C$ . The two possibilities for how the two corresponding arcs in  $D^2$  are identified to  $C$  are shown in Figure 3.2.

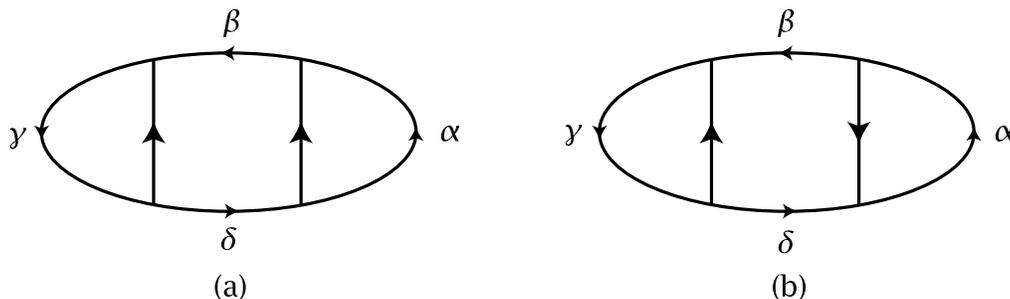

Figure 3.2

In either case, Figure 3.3 shows two ways to modify  $g_i$  to produce new immersions

$g'_i$  and  $g''_i$  eliminating the double arc  $C$ .

Figure 3.3

The claim is that either  $[g'_i | \partial D^2] \notin N_i$  or  $[g''_i | \partial D^2] \notin N_i$ . To see this, we break the loop  $g_i | \partial D^2$  up into four pieces  $\alpha, \beta, \gamma, \delta$  as indicated in Figure 3.2. Then in case (a) we have

$$\begin{aligned} \alpha\beta\gamma\delta &= (\alpha\gamma)\delta^{-1}(\alpha\beta^{-1}\gamma\delta^{-1})^{-1}(\alpha\gamma)\delta \\ &\quad \parallel \quad \parallel \quad \parallel \\ &\quad g'_i | \partial D^2 \quad g''_i | \partial D^2 \quad g'_i | \partial D^2 \end{aligned}$$

and in case (b) we have

$$\begin{aligned} \alpha\beta\gamma\delta &= (\alpha\gamma^{-1})(\gamma\delta)^{-1}(\alpha\gamma^{-1})^{-1}(\alpha\delta\gamma\beta)(\gamma\delta) \\ &\quad \parallel \quad \parallel \quad \parallel \\ &\quad g'_i | \partial D^2 \quad g'_i | \partial D^2 \quad g''_i | \partial D^2 \end{aligned}$$

So in either case, if  $g'_i | \partial D^2$  and  $g''_i | \partial D^2$  were both in the normal subgroup  $N_i$ , so would  $g_i | \partial D^2$  be in  $N_i$ .

We choose the new  $g_i$  to be either  $g'_i$  or  $g''_i$ , whichever one preserves the condition  $[g_i | \partial D^2] \notin N_i$ . Repeating this step, we eventually get  $g_i$  with  $p_i g_i$  an embedding  $g_{i-1}$ , with  $[g_{i-1} | \partial D^2] \notin N_{i-1}$ .  $\square$

**Corollary 3.2 (Dehn's Lemma).** *If an embedded circle in  $\partial M$  is nullhomotopic in  $M$ , it bounds a disk in  $M$ .*

**Proof:** First delete from  $\partial M$  everything but a neighborhood of the given circle  $C$ , producing a new manifold  $M'$  with  $\partial M'$  an annulus. (If  $C$  had a Möbius band neighborhood in  $\partial M$ , it would be an orientation-reversing loop in  $M$ , which is impossible since it is nullhomotopic.) Apply the loop theorem to  $M'$  to obtain a disk  $D^2 \subset M'$  with  $\partial D^2$  nontrivial in  $\partial M'$ , hence isotopic to  $C$ .  $\square$

**Corollary 3.3.** *Let  $S \subset M$  be a 2-sided surface. If the induced map  $\pi_1 S \rightarrow \pi_1 M$  is not injective for some choice of basepoint in some component of  $S$ , then there is a disk  $D^2 \subset M$  with  $D^2 \cap S = \partial D^2$  a nontrivial circle in  $S$ .*

**Proof:** Let  $f: D^2 \rightarrow M$  be a nullhomotopy of a nontrivial loop in  $S$ . We may assume  $f$  is transverse to  $S$ , so  $f^{-1}(S)$  consists of  $\partial D^2$  plus possibly some circles in  $D^2 - \partial D^2$ .

If such a circle in  $D^2 - \partial D^2$  gives a trivial loop in the component of  $S$  it maps to, then we can redefine  $f$  so as to eliminate this circle (and any other circles inside it) from  $f^{-1}(S)$ . So we may assume no circles of  $f^{-1}(S)$  are trivial in  $S$ . Then the restriction of  $f$  to the disk bounded by an innermost circle of  $f^{-1}(S)$  (this circle may be  $\partial D^2$  itself) gives a nullhomotopy in  $M - S$  of a nontrivial loop in  $S$ . Now apply the loop theorem to  $(M - \partial M) | (S - \partial S)$ .  $\square$

Here is another application of the loop theorem:

**Proposition 3.4.** *A compact connected orientable prime 3-manifold  $M$  with  $\pi_1 M \approx \mathbb{Z}$  is either  $S^1 \times S^2$  or  $S^1 \times D^2$ .*

**Proof:** First let us do the case  $\partial M \neq \emptyset$ . Then  $\partial M$  can contain no spheres, otherwise primeness would imply  $M = B^3$ , contradicting  $\pi_1 M \approx \mathbb{Z}$ . To restrict the possibilities for  $\partial M$  further we need the following basic result.

**Lemma 3.5.** *If  $M$  is a compact orientable 3-manifold then the image of the boundary map  $H_2(M, \partial M) \rightarrow H_1(\partial M)$  has rank equal to one half the rank of  $H_1(\partial M)$ .*

Here ‘rank’ means the number of  $\mathbb{Z}$  summands in a direct sum splitting into cyclic groups. Equivalently, we can use homology with  $\mathbb{Q}$  coefficients and replace ‘rank’ by ‘dimension.’

**Proof:** With  $\mathbb{Q}$  coefficients understood, consider the commutative diagram

$$\begin{array}{ccccc} H_2(M, \partial M) & \xrightarrow{\partial} & H_1(\partial M) & \xrightarrow{i_*} & H_1(M) \\ \wr & & \wr & & \wr \\ H^1(M) & \xrightarrow{i^*} & H^1(\partial M) & \xrightarrow{\delta} & H^2(M, \partial M) \end{array}$$

where the vertical isomorphisms are given by Poincaré duality. Since we have coefficients in a field, the map  $i^*$  is the dual of  $i_*$ , obtained by applying  $\text{Hom}(-, \mathbb{Q})$ . Linear algebra then implies that  $\dim \text{Ker } i_* = \dim \text{Coker } i^*$ . Hence  $\dim \text{Im } \partial = \dim \text{Ker } i_* = \dim \text{Coker } i^* = \dim \text{Coker } \partial$  which implies the result.  $\square$

Continuing with the proof of the Proposition,  $H_1(M)$  has rank one, hence so does  $H^1(M) \approx H_2(M, \partial M)$  and we conclude that  $\partial M$  must be a single torus. The map  $\pi_1 \partial M \rightarrow \pi_1 M$  is not injective, so the loop theorem gives a disk  $D^2 \subset M$  with  $\partial D^2$  nontrivial in  $\partial M$ . Splitting  $M$  along this  $D^2$  gives a manifold with boundary  $S^2$ , and this leads to a connected sum decomposition  $M = N \# S^1 \times D^2$ . Since  $M$  is prime, we conclude that  $M = S^1 \times D^2$ .

When  $\partial M = \emptyset$  we use another basic fact about 3-manifolds:

**Lemma 3.6.** *For a 3-manifold  $M$ , every class in  $H_2(M)$  is represented by an embedded closed orientable surface  $S \subset M$ , and similarly every class in  $H_2(M, \partial M)$  is represented by an embedded compact orientable surface  $(S, \partial S) \subset (M, \partial M)$ . If  $M$  is orientable,  $S$  may be chosen in both cases so that the inclusion of each component of  $S$  into  $M$  induces an injective map on  $\pi_1$ .*

**Proof:** Taking simplicial homology with respect to some triangulation of  $M$ , represent a class in  $H_2(M)$  by a cycle  $z$ , a sum of the oriented 2-simplices in  $M$  with integer coefficients. Reversing orientations of some simplices, we may assume all coefficients are non-negative. To desingularize this 2-cycle  $z$  into a surface, first replace each 2-simplex  $\sigma$  with coefficient  $n_\sigma$  by  $n_\sigma$  nearby parallel copies of itself, all with the same boundary  $\partial\sigma$ . Next, look in a small disk transverse to a 1-simplex of  $M$ . The copies of 2-simplices incident to this 1-simplex have induced normal orientations, which we can think of as either clockwise or counterclockwise around the 1-simplex. Since  $z$  is a cycle, the number of incident 2-simplices with clockwise orientation equals the number with counterclockwise orientation. Thus there must be two consecutive 2-simplices with opposite orientation. The edges of these along the given 1-simplex can be joined together and pushed off the 1-simplex. Repeat this step until  $z$  is ‘resolved’ to a surface whose only singularities are at vertices of  $M$ . To eliminate these isolated singularities, consider a small ball about a vertex. The surface meets the boundary of this ball in disjoint embedded circles, so we can cap off these circles by disjoint embedded disks in the interior of the ball. Doing this for all vertices produces an embedded oriented surface  $S$ , with a natural map to the 2-skeleton of  $M$  taking the fundamental class for  $S$  to  $z$ . The case of relative homology is treated in similar fashion.

To obtain the final statement of the lemma, suppose the map  $\pi_1 S \rightarrow \pi_1 M$  is not injective for some component of  $S$ . Then Corollary 3.3 gives a disk  $D \subset M$  realizing this noninjectivity. Surgering  $S$  along  $D$  produces a new surface which is obviously in the same homology class. Since  $S$  is compact, surgery simplifies  $S$ , either splitting one component into two components of lower genus, in case  $\partial D$  separates  $S$ , or in the opposite case, reducing the genus of a component of  $S$ . So after finitely many steps we reach the situation that each component of  $S$  is  $\pi_1$ -injective.  $\square$

Returning to the proof of Proposition 3.4 in the case of closed  $M$ , we have  $\mathbb{Z} \approx H_1(M) \approx H^1(M) \approx H_2(M)$ . By the lemma we may represent a nontrivial class in  $H_2(M)$  by a closed embedded surface  $S$  with each component  $\pi_1$ -injective. Since  $\pi_1 M \approx \mathbb{Z}$ , each component of  $S$  must then be a 2-sphere. The separating spheres are

trivial in homology, so can be discarded, leaving at least one nonseparating sphere. As in Proposition 1.4 this gives a splitting  $M = N \# S^1 \times S^2$ , finishing the proof.  $\square$

Dropping the hypothesis that  $M$  is prime, the proof shows that  $M = N \# S^1 \times S^2$  or  $N \# S^1 \times D^2$ . Then  $\pi_1 M \approx \pi_1 N * \mathbb{Z}$ , hence  $N$  is simply-connected, since a nontrivial free product is necessarily nonabelian. This implies that  $\partial N$ , hence also  $\partial M$ , consists of spheres, since as we showed in the proof of the loop theorem,  $H_1(N; \mathbb{Z}_2) = 0$  is sufficient to obtain this conclusion. Let  $N'$  be obtained from  $N$  by capping off its boundary spheres by balls. Thus  $N'$  is a closed simply-connected 3-manifold. The next proposition describes the homotopy type of such an  $N'$ .

**Proposition 3.7.** *A closed simply-connected 3-manifold is a homotopy sphere, i.e., homotopy equivalent to  $S^3$ . A compact 3-manifold is contractible if and only if it is simply-connected and has boundary a 2-sphere.*

**Proof:** Let  $P$  be a closed simply-connected 3-manifold. It is orientable since  $\pi_1 P = 0$ . By Poincaré duality and the Hurewicz theorem we have  $\pi_2 P \approx H_2(P) \approx H^1(P) \approx H_1(P) = 0$ . Then  $\pi_3 P \approx H_3(M) \approx \mathbb{Z}$ , and we have a degree one map  $S^3 \rightarrow P$ . This induces an isomorphism on all homology groups. Since both  $S^3$  and  $P$  are simply-connected, Whitehead's theorem implies that the map  $S^3 \rightarrow P$  is a homotopy equivalence.

The second assertion can be proved in similar fashion.  $\square$

The Poincaré Conjecture (still unproved) is the assertion that  $S^3$  is the only homotopy 3-sphere, or equivalently,  $B^3$  is the only compact contractible 3-manifold.

## The Sphere Theorem

Here is the general statement:

**Theorem 3.8.** *Let  $M$  be a connected 3-manifold. If  $\pi_2 M \neq 0$ , then either*

- (a) *there is an embedded  $S^2$  in  $M$  representing a nontrivial element in  $\pi_2 M$ , or*
- (b) *there is an embedded 2-sided  $\mathbb{R}P^2$  in  $M$  such that the composition of the cover  $S^2 \rightarrow \mathbb{R}P^2$  with the inclusion  $\mathbb{R}P^2 \hookrightarrow M$  represents a nontrivial element of  $\pi_2 M$ .*

A 2-sided  $\mathbb{R}P^2 \subset M$  can exist only if  $M$  is nonorientable, so for orientable  $M$  the theorem asserts that there is an  $S^2 \subset M$  which is nontrivial in  $\pi_2 M$ , if  $\pi_2 M$  is nonzero. An example of a nonorientable manifold where  $\mathbb{R}P^2$ 's are needed to represent a nontrivial element of  $\pi_2$  is  $S^1 \times \mathbb{R}P^2$ . This has  $S^1 \times S^2$  as a double cover, so  $\pi_2$

is  $\mathbb{Z}$ . However,  $S^1 \times \mathbb{R}P^2$  is irreducible, by Proposition 1.13, so any embedded  $S^2$  in  $S^1 \times \mathbb{R}P^2$  is nullhomotopic.

We remark that it is not true in general for orientable  $M$  that every element of  $\pi_2 M$  is represented by an embedded sphere. For example,  $\pi_2(S^1 \times S^2) \approx \mathbb{Z}$ , but as we saw in Proposition 1.4, a separating  $S^2$  in  $S^1 \times S^2$  bounds a ball since  $S^1 \times S^2$  is prime, while a nonseparating  $S^2$  is a slice  $\{x\} \times S^2$  in a product structure  $S^1 \times S^2$  hence represents a generator of  $\pi_2$ .

**Corollary 3.9.** *Let  $M$  be a compact connected orientable irreducible 3-manifold with universal cover  $\tilde{M}$ .*

- (a) *If  $\pi_1 M$  is infinite, and in particular if  $\partial M \neq \emptyset$ , then  $M$  is a  $K(\pi, 1)$ , i.e.,  $\pi_i M = 0$  for all  $i > 1$ , or equivalently,  $\tilde{M}$  is contractible.*
- (b) *If  $\pi_1 M$  is finite, then either  $M = B^3$  or  $M$  is closed and  $\tilde{M}$  is a homotopy 3-sphere.*

**Proof:** Since  $M$  is irreducible, the Sphere Theorem implies that  $\pi_2 M$  is zero. It follows that  $\pi_3 M \approx \pi_3 \tilde{M} \approx H_3 \tilde{M}$  by the Hurewicz theorem. If  $\pi_1 M$  is infinite,  $\tilde{M}$  is noncompact, so  $H_3 \tilde{M} = 0$ . Thus  $\pi_3 M = 0$ . By Hurewicz again,  $\pi_4 M \approx \pi_4 \tilde{M} \approx H_4 \tilde{M}$ . Since  $H_4$  of a 3-manifold is zero, we get  $\pi_4 M = 0$ . Similarly, all higher homotopy groups of  $M$  are zero. Now assume  $\pi_1 M$  is finite. If  $\partial M \neq \emptyset$  then by Lemma 3.5,  $\partial M$  must consist of spheres and irreducibility implies  $M = B^3$ . If  $\partial M = \emptyset$ , then  $\tilde{M}$  is also closed since the covering  $\tilde{M} \rightarrow M$  is finite-sheeted, and so by Proposition 3.7  $\tilde{M}$  is a homotopy sphere.  $\square$

**Proposition 3.10.** *An embedded sphere  $S^2 \subset M$  is zero in  $\pi_2 M$  if and only if it bounds a compact contractible submanifold of  $M$ . A 2-sided  $\mathbb{R}P^2 \subset M$  is always nontrivial in  $\pi_2 M$ .*

**Proof:** Let  $\tilde{S}$  be any lift of the nullhomotopic sphere  $S \subset M$  to the universal cover  $\tilde{M}$ . Via the isomorphism  $\pi_2 M \approx \pi_2 \tilde{M}$ ,  $\tilde{S}$  is nullhomotopic in  $\tilde{M}$ , hence it is also homologically trivial in  $\tilde{M}$ , bounding a compact submanifold  $\tilde{N}$  of  $\tilde{M}$ . Rechoosing  $\tilde{S}$  to be an innermost lift of  $S$  in  $\tilde{N}$ , we may assume  $\tilde{N}$  contains no other lifts of  $S$ . Then the restriction of the covering projection  $\tilde{M} \rightarrow M$  to  $\tilde{N}$  is a covering space  $\tilde{N} \rightarrow N$ , as in the proof of Proposition 1.6. This covering is 1-sheeted, i.e., a homeomorphism, since it is 1-sheeted over  $S$ . By the van Kampen theorem,  $\tilde{N}$  is simply-connected since  $\tilde{M}$  is. By Proposition 3.7,  $N$  is contractible.

For the case of a 2-sided  $\mathbb{R}P^2 \subset M$ , consider the orientable double cover  $\tilde{M} \rightarrow M$ , corresponding to the subgroup of  $\pi_1 M$  represented by orientation-preserving loops in  $M$ . The given  $\mathbb{R}P^2$  lifts to a unique  $S^2 \subset \tilde{M}$ . If this is nullhomotopic, the first

half of the proposition implies that this  $S^2$  bounds a contractible submanifold  $\tilde{N}$  of  $\tilde{M}$ . The nontrivial deck transformation of  $\tilde{M}$  takes  $\tilde{N}$  to itself since the given  $\mathbb{R}P^2$  is 2-sided in  $M$ . So the restriction of the covering projection to  $\tilde{N}$  is a double cover  $\tilde{N} \rightarrow N$ , with  $\partial N = \mathbb{R}P^2$ . This is impossible by the following lemma. (Alternatively, the Lefschetz fixed point theorem implies that the nontrivial deck transformation  $\tilde{N} \rightarrow \tilde{N}$  must have a fixed point since  $\tilde{N}$  is contractible.)  $\square$

**Lemma 3.11.** *If  $N$  is a compact 3-manifold, then the Euler characteristic  $\chi(\partial N)$  is even.*

**Proof:** By the proof of Lemma 3.5 with  $\mathbb{Z}_2$  coefficients now instead of  $\mathbb{Q}$  coefficients, we see that  $H_1(\partial N; \mathbb{Z}_2)$  is even-dimensional, from which the result follows.  $\square$

The converse statement, that a closed surface of even Euler characteristic is the boundary of some compact 3-manifold, is easily seen to be true also.

Here is another consequence of the Sphere Theorem:

**Proposition 3.12.** *In a compact orientable 3-manifold  $M$  there exists a finite collection of embedded 2-spheres generating  $\pi_2 M$  as a  $\pi_1 M$ -module.*

**Proof:** By the prime decomposition there is a finite collection  $S$  of disjoint spheres in  $M$  such that each component of  $M|S$  is an irreducible manifold with punctures. We claim that the spheres in  $S$ , together with all the spheres in  $\partial M$ , generate  $\pi_2 M$  as a  $\pi_1 M$ -module. For let  $f: S^2 \rightarrow M$  be given. Perturb  $f$  to be transverse to  $S$ , so that  $f^{-1}(S)$  is a collection of circles in  $S^2$ . Since the components of  $S$  are simply-connected, we may homotope  $f$ , staying transverse to  $S$ , so that  $f$  takes each circle in  $f^{-1}(S)$  to a point. This means that  $f$  is homotopic to a linear combination, with coefficients in  $\pi_1 M$ , of maps  $f_j: S^2 \rightarrow M - S$ . It suffices now to show that if  $P$  is irreducible-with-punctures then  $\pi_2 P$  is generated as a  $\pi_1 P$ -module by the spheres in  $\partial P$ . This is equivalent to saying that if  $\tilde{P} \rightarrow P$  is the universal cover, then  $\pi_2 \tilde{P}$  is generated by the spheres in  $\partial \tilde{P}$ . To show this, let  $\tilde{P}'$  be  $\tilde{P}$  with its boundary spheres filled in with balls  $B_\ell$ . We have a Mayer-Vietoris sequence:

$$\begin{array}{ccccc} & & 0 & & \\ & & \parallel & & \\ H_2(\cup_\ell \partial B_\ell) & \longrightarrow & H_2(\cup_\ell B_\ell) \oplus H_2(\tilde{P}) & \longrightarrow & H_2(\tilde{P}') \\ & \wr & \wr & & \wr \\ \pi_2(\cup_\ell \partial B_\ell) & \longrightarrow & \pi_2(\tilde{P}) & \longrightarrow & \pi_2(\tilde{P}') \end{array}$$

Now  $\tilde{P}'$  is the universal cover of the irreducible manifold  $P'$  obtained by filling in the boundary spheres of  $P$ , so  $\pi_2 \tilde{P}' \approx \pi_2 P' = 0$  by the Sphere Theorem. Since

$H_2(\bigcup_\ell B_\ell) = 0$ , we conclude that  $\pi_2(\bigcup_\ell \partial B_\ell) \rightarrow \pi_2(\tilde{P})$  is surjective, i.e.,  $\pi_2\tilde{P}$  is generated by the spheres in its boundary.  $\square$

**Proof of the Sphere Theorem:** Let  $p: \tilde{M} \rightarrow M$  be the universal cover. By Lemma 3.6 we may represent a nonzero class in  $\pi_2 M \approx \pi_2 \tilde{M} \approx H_2 \tilde{M}$  by an embedded closed orientable surface  $S \subset \tilde{M}$ , each component of which is  $\pi_1$ -injective, hence a sphere since  $\pi_1 \tilde{M} = 0$ . Some component will be nontrivial in  $H_2 \tilde{M}$ , hence in  $\pi_2 \tilde{M}$ . Call this component  $S_0$ .

The rest of the proof will be to show that the sphere  $S_0$  can be chosen so that the union of all the images  $\tau(S_0)$  under the deck transformations  $\tau$  of  $\tilde{M}$  is a collection of disjoint embedded spheres. Then the restriction  $p: S_0 \rightarrow p(S_0)$  is a covering space, so its image  $p(S_0)$  is an embedded  $S^2$  or  $\mathbb{R}P^2$  in  $M$  representing a nontrivial element of  $\pi_2 M$ . If it is a 1-sided  $\mathbb{R}P^2$ , then the boundary of an  $I$ -bundle neighborhood of this  $\mathbb{R}P^2$  is an  $S^2$  with the inclusion  $S^2 \hookrightarrow M$  homotopic to the composition  $S_0 \rightarrow \mathbb{R}P^2 \hookrightarrow M$ , hence nontrivial in  $\pi_2 M$  by the choice of  $S_0$ . Thus the proof will be finished.

We now introduce the key technical ideas which will be used. Let  $N$  be a triangulated 3-manifold, with triangulation  $\mathcal{T}$ . Then a surface  $S \subset N$  is said to be in **normal form** with respect to the triangulation if it intersects each 3-simplex  $\Delta^3$  of  $\mathcal{T}$  in a finite collection of disks, each disk being bounded by a triangle or square of one of the types shown in Figure 3.4.

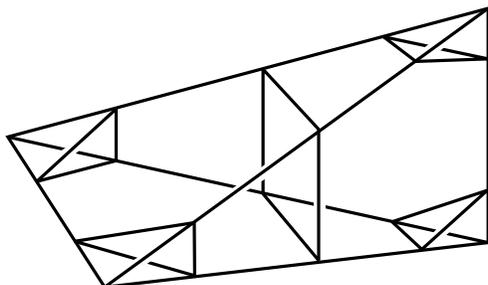

Figure 3.4

There are four types of triangles in each  $\Delta^3$  separating one vertex from the other three, and three types of squares separating opposite pairs of edges of  $\Delta^3$ . Squares of different types necessarily intersect each other, so an embedded surface in normal form can contain squares of only one type in each  $\Delta^3$ . The edges of the squares and triangles are assumed to be straight line segments, so ‘triangles’ are literally triangles, but ‘squares’ do not have to lie in a single plane or have all four sides of equal length. ‘Quadrilateral’ would thus be a more accurate term.

For a compact surface  $S$  which meets the 1-skeleton of the triangulation trans-

versely we define the **weight**  $w(S)$  to be the total number of points of intersection of  $S$  with all the edges of the triangulation.

**Lemma 3.13.** *If  $N$  contains an embedded sphere which is nontrivial in  $\pi_2 N$ , then it contains such a sphere in normal form, and we may take this sphere to have minimal weight among all spheres which are nontrivial in  $\pi_2 N$ .*

**Proof:** As in the proof of existence of prime decompositions, we begin by perturbing a nontrivial sphere  $S \subset N$  to be transverse to all simplices of  $\mathcal{T}$ , and then we perform surgeries to produce an  $S$  meeting each 3-simplex only in disks. A surgery on  $S$  produces a pair of spheres  $S'$  and  $S''$ , and in  $\pi_2 N$ ,  $S$  is the sum of  $S'$  and  $S''$ , with respect to suitably chosen orientations and paths to a basepoint. So at least one of  $S'$  and  $S''$  must be nontrivial in  $\pi_2 N$  if  $S$  is, and we replace  $S$  by this nontrivial  $S'$  or  $S''$ . Then we repeat the process until we obtain a nontrivial sphere  $S$  meeting all 3-simplices in disks. Note that replacing  $S$  by  $S'$  or  $S''$  does not yield a sphere of larger weight since  $w(S) = w(S') + w(S'')$ .

Next, we isotope  $S$  so that for each 3-simplex  $\Delta^3$ , the boundary  $\partial D$  of each disk component  $D$  of  $S \cap \Delta^3$  meets each edge of  $\Delta^3$  at most once. For if such a circle  $\partial D$  meets an edge  $\Delta^1$  more than once, consider two points of  $\partial D \cap \Delta^1$ . After rechoosing these two points if necessary, we may assume the segment  $\alpha$  of  $\Delta^1$  between these points meets  $D$  only in the two points of  $\partial\alpha$ . The arc  $\alpha$  lies in one of the two disks of  $\partial\Delta^3$  bounded by  $\partial D$ , and separates this disk into two subdisks. Let  $E$  be one of these subdisks. We may perturb  $E$  so that it lies entirely in the interior of  $\Delta^3$  except for the arc  $\alpha$  in  $\partial E$ , which we do not move, and so that the rest of  $\partial E$ , an arc  $\beta$ , stays in  $D$ . Now we can perform an isotopy of  $S$  which removes the two points of  $\partial\alpha = \partial\beta$  from the intersection of  $S$  with the edge  $\Delta^1$  by pushing  $\beta$  across the repositioned  $E$ . It may be that before this isotopy,  $E$  intersects  $S$  in other curves besides  $\beta$ , but this is not a real problem as we can just push these curves along ahead of the moving  $\beta$ . The key property of this isotopy is that it decreases the weight  $w(S)$  by at least two, since it eliminates the two intersection points of  $\partial\alpha$  without introducing any new intersections of  $S$  with edges of the triangulation.

Since this isotopy decreases  $w(S)$ , finitely many such isotopies, interspersed with the former surgery steps to make  $S$  meet each 3-simplex in disks, suffice to produce a sphere  $S$  meeting 3-simplices only in disks, with the boundaries of these disks meeting each 1-simplex at most once. We can then easily isotope  $S$  to meet all 2-simplices in straight line segments, without changing the intersections with edges. We leave it as an exercise for the reader to check that the condition that the boundary circles of the

disks of  $S \cap \Delta^3$  meet each 1-simplex at most once implies that each of these boundary circles consists of either three or four segments, forming a triangle or square as in Figure 3.4.

Thus we produce a sphere  $S$  in normal form which is still nontrivial in  $\pi_2 N$ . Since the procedure for doing this did not increase the weight of  $S$ , it follows that the minimum weight of all homotopically nontrivial spheres in  $N$  is achieved by a normal form nontrivial sphere.  $\square$

Now we return to the proof of the Sphere Theorem. Choose a triangulation of  $M$  and lift this to a triangulation  $\mathcal{T}$  of  $\widetilde{M}$ . By the preceding lemma we may take  $S_0$  to be in normal form with respect to  $\mathcal{T}$  and of minimum weight among all nontrivial spheres in  $\widetilde{M}$ . The immersed sphere  $p(S_0) \subset M$  is then composed of triangles and squares in all the 3-simplices of  $M$ , and by small perturbations of the vertices of these triangles and squares we can put their boundary edges in general position with respect to each other. This means that any two edges of triangles or squares meet transversely in at most one point lying in the interior of a 2-simplex, and no three edges have a common point. We may also assume the interiors of the triangles and squares intersect each other transversely. Lifting back up to  $\widetilde{M}$ , this means that the collection  $\Sigma$  of all the translates  $\tau(S_0)$  of  $S_0$  under deck transformations  $\tau \in \pi_1 M$  consists of minimum weight nontrivial spheres in normal form, having transverse intersections disjoint from the 1-skeleton of  $\mathcal{T}$ .

Define compact subsets  $B_i \subset \widetilde{M}$  inductively, letting  $B_0$  be any 3-simplex of  $\mathcal{T}$  and then letting  $B_i$  be the union of  $B_{i-1}$  with all 3-simplices which meet  $B_{i-1}$ . So  $B_0 \subset B_1 \subset \cdots \subset \bigcup_i B_i = \widetilde{M}$ . Let  $\Sigma_i$  be the collection of all the spheres in  $\Sigma$  which meet  $B_i$ . This is a finite collection since only finitely many  $\tau(S_0)$ 's meet each 3-simplex of  $\mathcal{T}$ , and  $B_i$  is a finite union of 3-simplices.

We describe now a procedure for modifying the spheres in  $\Sigma_i$  to make them all disjoint. Suppose  $S \cap S' \cap \mathcal{T}^2 \neq \emptyset$  for some  $S, S' \in \Sigma_i$ , where  $\mathcal{T}^2$  denotes the 2-skeleton of  $\mathcal{T}$ . As a first step, circles of  $S \cap S'$  in the interiors of 3-simplices of  $\mathcal{T}$  can be eliminated by isotopy of  $S$  without affecting  $S \cap \mathcal{T}^2$ . Namely, since  $S$  and  $S'$  are in normal form, such a circle in a simplex  $\Delta^3$  bounds disks  $D \subset S \cap \Delta^3$  and  $D' \subset S' \cap \Delta^3$ . We may choose  $D$  to be innermost, so that  $D \cap S' = \partial D$ . Then  $D \cup D'$  is a sphere, which bounds a ball in  $\Delta^3$  by Alexander's theorem, and we can isotope  $S'$  by pushing  $D'$  across this ball to eliminate the circle  $\partial D = \partial D'$  from  $S \cap S'$ .

Next we will appeal to the following crucial lemma:

**Lemma 3.14.** *Let  $S$  and  $S'$  be minimum weight nontrivial spheres in normal form, intersecting transversely and with  $S \cap S'$  disjoint from 1-simplices. Assume that  $S \cap S' \neq \emptyset$ , and that in each 3-simplex,  $S \cap S'$  consists only of arcs, no circles. Then there is a circle  $C$  of  $S \cap S'$  which is innermost in both  $S$  and  $S'$ , i.e.,  $C$  bounds disks  $D \subset S$  and  $D' \subset S'$  with  $D \cap S' = \partial D$  and  $D' \cap S = \partial D'$ . Furthermore we may choose  $D$  and  $D'$  so that the sphere  $D \cup D'$  is trivial in  $\pi_2 M$ .*

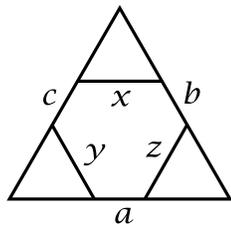

Let us postpone the proof of this lemma, which is rather lengthy, and continue with the proof of the Sphere Theorem. Having a circle  $C$  as in this lemma, we replace  $D$  by  $D'$  in  $S$  to obtain a new sphere  $S$ , and similarly modify  $S'$  by replacing  $D'$  by  $D$ . Since  $D \cup D'$  is trivial, the new spheres  $S$  and  $S'$  are homotopic to the old ones, hence are nontrivial. They are also still of minimum weight since the total weight  $w(S) + w(S')$  is unchanged, hence both terms are unchanged since  $S$  and  $S'$  each have minimal weight. With a small perturbation of  $S$  and  $S'$  we can eliminate the circle  $C$  from  $S \cap S'$ . The new spheres  $S$  and  $S'$  are not in normal form, but can easily be made so: First straighten their arcs of intersection with 2-simplices without changing the endpoints of these arcs; note that these arcs must join distinct edges of each 2-simplex, otherwise  $S$  or  $S'$  would not be of minimum weight. Having straightened the intersection of  $S$  and  $S'$  with 2-simplices, the intersections of  $S$  and  $S'$  with 3-simplices must still be disks, otherwise the procedure for putting them into normal form would decrease their weights, which is not possible. The new  $S$  and  $S'$  together have no more points of intersection in 2-simplices with other spheres in  $\Sigma_i$  than the old  $S$  and  $S'$  did, since these other spheres are in normal form, so when we straightened the intersections of the new  $S$  and  $S'$  with 2-simplices this will not produce new intersections with the other spheres.

Thus by repeating this process for the other circles of  $S \cap S'$  and then for all pairs  $S, S'$ , in  $\Sigma_i$  we eventually obtain a collection  $\Sigma_i$  of spheres which are disjoint in all 2-simplices. They can easily be made to be disjoint in the interior of each 3-simplex  $\Delta^3$  as well. For the new spheres of  $\Sigma_i$  meet  $\partial\Delta^3$  in a collection of disjoint circles, so we need only choose disjoint disks in  $\Delta^3$  bounded by these circles, then isotope the disks of  $\Sigma_i \cap \Delta^3$  to these disjoint disks,  $\text{rel } \Sigma_i \cap \partial\Delta^3$ .

Suppose we perform this disjunction procedure on the spheres in  $\Sigma_0, \Sigma_1, \Sigma_2, \dots$  in turn. We claim that no sphere is modified infinitely often. To see this, observe first that each sphere of  $\Sigma_i$  is contained in  $B_{i+w}$  where  $w$  is the common weight of all the spheres of  $\Sigma$ . This is because the cell structure on each sphere  $S$  in  $\Sigma$  consisting of the triangles and squares given by normal form has  $w$  vertices, so a maximal tree in

its 1-skeleton has  $w - 1$  edges and any two vertices can be joined by an edgepath with  $w - 1$  edges, so if  $S$  meets  $B_i$ ,  $S$  must be contained in  $B_{i+w}$ . So a sphere in  $\Sigma_i$  will not be modified at any stage after the spheres which meet  $B_{i+w}$  are modified, i.e., the spheres in  $\Sigma_{i+w}$ .

So the infinite sequence of modifications produces a collection  $\Sigma$  of disjoint non-trivial spheres. Let  $S$  denote the union of these spheres. This is a surface in normal form, perhaps noncompact. We claim that the intersection of  $S$  with the 2-skeleton  $\mathcal{T}^2$  is invariant under all the deck transformation. This is certainly true for the intersection with the 1-skeleton  $\mathcal{T}^1$ , which was unchanged during the whole modification procedure. Observe that for a surface  $T$  in normal form,  $T \cap \mathcal{T}^1$  determines  $T \cap \mathcal{T}^2$  uniquely, since for each simplex  $\Delta^2$ , the weights  $a, b, c$  of  $T$  at the three edges of  $\Delta^2$  determine the numbers  $x, y, z$  of arcs of  $T \cap \Delta^2$  joining each pair of edges, as indicated in Figure 3.5.

$$\begin{aligned} x + y &= c & x &= \frac{1}{2}(b + c - a) \\ x + z &= b & y &= \frac{1}{2}(a + c - b) \\ y + z &= a & z &= \frac{1}{2}(a + b - c) \end{aligned}$$

Figure 3.5

So for each deck transformation  $\tau$ , the normal form surfaces  $S$  and  $\tau(S)$  have the same intersection with  $\mathcal{T}^1$  hence also with  $\mathcal{T}^2$ , as claimed.

Finally, to make  $S$  itself invariant under deck transformations we need only choose the disks of  $S - \mathcal{T}^2$  to be invariant. This can be done by fixing a choice of these disks in a particular 3-simplex of  $\mathcal{T}$  lying over each 3-simplex in  $M$ , then translating these disks to all other 3-simplices of  $\mathcal{T}$  via the deck transformations.  $\square$

**Proof of Lemma 3.14:** Consider disks  $D \subset S$  and  $D' \subset S'$  bounded by circles of  $S \cap S'$ . Such disks may or may not be innermost, i.e., meeting  $S \cap S'$  only in their boundary. Here are some facts about such disks.

(1) The minimum weight of disks in  $S$  and  $S'$  is the same. For consider a disk of minimum weight in both  $S$  and  $S'$ , say  $D \subset S$ . We may assume  $D$  is innermost. Let  $D'$  and  $E'$  be the disks in  $S'$  bounded by  $\partial D$ . At least one of the spheres  $D \cup D'$ ,  $D \cup E'$  is nontrivial, say  $D \cup E'$ . Then  $w(D \cup E') \geq w(S') = w(D' \cup E')$  since  $S'$  has minimal weight. Weights being additive, we get  $w(D) \geq w(D')$ . This implies  $w(D) = w(D')$  by the choice of  $D$ , so  $D'$  also achieves the minimum weight of disks

in  $S$  and  $S'$ .

(2) If  $D \subset S$  is an innermost minimum weight disk, separating  $S'$  into disks  $D'$  and  $E'$  with  $D \cup E'$  nontrivial, then  $D'$  is a minimum weight disk and  $D \cup E'$  is a minimum weight nontrivial sphere. This was shown in (1) except for the observation that  $D \cup E'$  is minimum weight, which holds because  $w(D \cup E') = w(D' \cup E')$  since  $w(D) = w(D')$ .

(3) Each disk  $D$  has  $w(D) > 0$ . To verify this we may assume  $D$  is innermost. The normal form sphere  $S$  is decomposed into triangles and squares by the 2-skeleton  $\mathcal{T}^2$ . If  $w(D) = 0$ ,  $D$  is disjoint from the corners of these triangles and squares, and so meets them in regions of the following types:

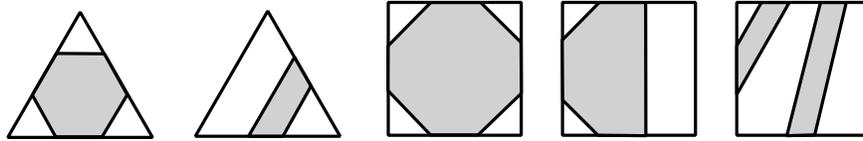

Figure 3.6

Construct a graph  $G \subset D$  by placing a vertex in the interior of each of these regions, together with an edge joining this vertex to the midpoint of each of the arcs of intersection of the region with the sides of the triangle or square. Clearly  $D$  deformation retracts onto  $G$ , so  $G$  is a tree, but this contradicts the fact that each vertex of  $G$  is incident to at least two edges of  $G$ .

(4) By (3), a minimum weight disk  $D$  which is not innermost can contain only one innermost disk  $D_0$ , and the annuli in  $D - D_0$  bounded by circles of  $S \cap S'$  must have weight zero. By the Euler characteristic argument in (3), these annuli must consist entirely of the rectangular shaded regions in Figure 3.6.

(5) For a minimum weight disk  $D$ , there must exist in some 2-simplex  $\Delta^2$  of  $\mathcal{T}$  an arc component  $\alpha$  of  $D \cap \Delta^2$  having one end on  $\partial\Delta^2$  and the other in the interior of  $\Delta^2$ . This is because  $D$  meets  $\mathcal{T}^1$  (since  $w(D) > 0$ ), and if a component of  $D \cap \mathcal{T}^2$  containing a point of  $D \cap \mathcal{T}^1$  consisted entirely of arc components of  $D \cap \Delta^2$  with both endpoints on  $\partial\Delta^2$ , for each  $\Delta^2$ , then  $D$  would be a closed surface.

(6) An arc  $\alpha$  as in (5) is divided into segments by the points of  $\alpha \cap S'$ . Each such segment, except the one meeting  $\partial\Delta^2$ , must connect the two boundary components of an annulus of  $D - S'$ , as in (4). The segment of  $\alpha$  meeting  $\partial\Delta^2$  must lie in the unique innermost disk  $D_0 \subset D$ .

Having these various facts at our disposal, we now begin the proof proper.

*Case I.* Suppose we have a minimum weight disk  $D$  and an arc  $\alpha$  of  $D \cap \Delta^2$  as in (5) with the additional property that the endpoint of  $\alpha$  in the interior of  $\Delta^2$  is the endpoint of an arc  $\alpha'$  of  $S' \cap \Delta^2$  whose other endpoint lies on the same edge of  $\Delta^2$  as the other endpoint of  $\alpha$ ; see Fig. 3.6a. The two arcs  $\alpha$  and  $\alpha'$  cut off a triangle  $T$  from  $\Delta^2$ , and the following argument will involve replacing  $T$  by subtriangles until the situation of Fig. 3.7c is achieved, with  $\alpha \cap S' = \alpha' \cap S = \alpha \cap \alpha'$ .

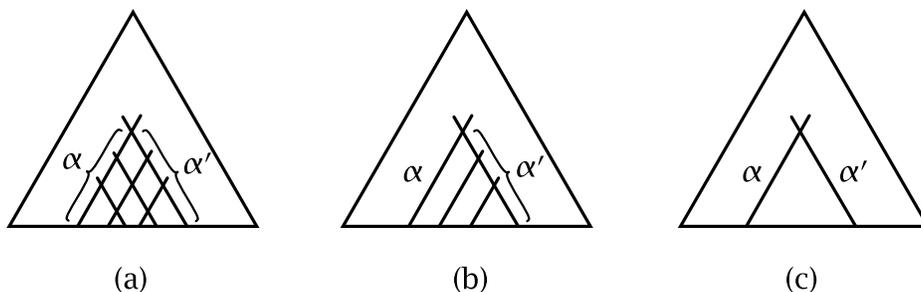

Figure 3.7

After replacing  $D$  by its innermost subdisk we may assume by (6) that  $\alpha \cap S' = \alpha \cap \alpha'$ , as in Fig. 3.7b. Near  $\alpha \cap \alpha'$ ,  $\alpha'$  lies in a disk  $D' \subset S'$ . If all of  $\alpha'$  is not contained in  $D'$ , then the circle  $\partial D = \partial D'$  meets  $\alpha'$  at another point in the interior of  $\alpha'$ , and we can rechoose  $\alpha$  to have this point as an endpoint. So we may assume  $\alpha' \subset D'$ . If  $D \cup D'$  is nontrivial, relabel  $D'$  as  $E'$  in the notation of (1) and (2) above. But then the minimum weight nontrivial sphere  $D \cup E'$  can obviously be isotoped to decrease its weight, a contradiction. So  $D \cup D'$  is trivial, and by (1)  $D'$  is also a minimum weight disk. We can then repeat the preceding steps with the roles of  $D$  and  $D'$  reversed, obtaining in the end the desired situation of Fig. 3.7c, with both  $D$  and  $D'$  innermost and minimum weight, and  $D \cup D'$  trivial. This finishes the proof in Case I.

*Case II.* Suppose we have a minimum weight disk  $D$  such that  $D \cap \Delta^2$  has a component which is an arc  $\beta$  in the interior of  $\Delta^2$ , for some 2-simplex  $\Delta^2$  of  $\mathcal{T}$ . The arc  $\beta$  is divided into segments by the points of  $S' \cap D$ . One of these segments must lie in the innermost disk  $D_0$  in  $D$ , otherwise these segments would all be arcs crossing the annuli of  $D - S'$  as we saw in (4), an impossibility since both ends of  $\beta$  are on  $\partial D$ . Replace  $D$  by its innermost disk, with the new  $\beta$  a subsegment of the old one. The two endpoints of  $\beta$  are joined to  $\partial \Delta^2$  by arcs  $\alpha_1$  and  $\alpha_2$  of  $S' \cap \Delta^2$ , which may be chosen to have their outer endpoints on the same edge of  $\Delta^2$ , as in Figure 3.8a.

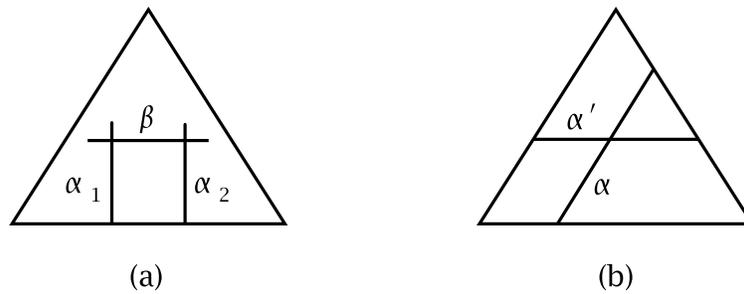

Figure 3.8

If there are other arcs of  $D \cap \Delta^2$  meeting  $\alpha_1$  or  $\alpha_2$ , these arcs cannot cross  $\alpha_1$  or  $\alpha_2$  since  $D$  is innermost. Furthermore, these arcs must lie on the same side of  $\alpha_1$  and  $\alpha_2$  as  $\beta$  since  $D$  lies on one side of  $S'$  near  $\partial D$ . Assuming we are not in Case I, these arcs then join  $\alpha_1$  to  $\alpha_2$ , and we can replace  $\beta$  by an edgemoast such arc joining  $\alpha_1$  to  $\alpha_2$ . So we may assume  $\alpha_1$  and  $\alpha_2$  meet  $D$  only at  $\partial\beta$ . Then  $\alpha_1$  and  $\alpha_2$  lie in a disk  $D'$  of  $S'$ . If the sphere  $D \cup D'$  is nontrivial, it must be minimum weight, by (2). But there is an obvious isotopy of  $D \cup D'$  decreasing its weight by two. So  $D \cup D'$  is trivial and  $D'$  is a minimum weight disk, by (2) again. If  $D'$  is innermost, we are done. Otherwise, replace  $D'$  by its innermost subdisk,  $\alpha_1$  and  $\alpha_2$  being replaced by subarcs which still meet  $\partial\Delta^2$  by (6). If we are not in Case I, the endpoints of  $\alpha_1$  and  $\alpha_2$  in the interior of  $\Delta^2$  are then joined by a new arc  $\beta$  in some disk  $D$  of  $S$  with  $\partial D = \partial D'$ . By (2) the sphere  $D \cup D'$  cannot be nontrivial, since there is an obvious isotopy decreasing its weight. So  $D \cup D'$  is trivial and  $D$  is minimum weight. If  $D$  is not innermost we can go back to the beginning of Case II and repeat the argument with a smaller rectangle bounded by  $\alpha_1 \cup \beta \cup \alpha_2$  in  $\Delta^2$ . So we may assume  $D$  is innermost, finishing the proof in Case II.

*Case III.* Considering again an arc  $\alpha$  as in (5), there remains the possibility that the component  $A'$  of  $S' \cap \Delta^2$  containing the endpoint of  $\alpha$  in the interior of  $\Delta^2$  has both its endpoints on edges of  $\Delta^2$  not containing the other endpoint of  $\alpha$ . Thus we have the configuration shown in Figure 3.8b. The arc  $\alpha$  lies in a minimum weight disk  $D$  which we may assume is innermost. In particular this means that no arcs of  $S' \cap \Delta^2$  below  $A'$  join the left and right edges of  $\Delta^2$ . By (2) we have  $\partial D = \partial D'$  for some minimum weight disk  $D'$  in  $S'$ . Assuming Cases I and II are not applicable, there is an arc  $\alpha'$  in  $D'$  as shown in the figure, with one endpoint at the upper endpoint of  $\alpha$  and the other endpoint in the left edge of  $\Delta^2$ . If  $D'$  is not innermost we may replace it by an innermost disk, choosing a new  $\alpha$  to the left of the current one. Thus we may assume both  $D$  and  $D'$  are innermost. If  $D \cup D'$  is nontrivial then by (2) we can

rechoose  $D'$  on the other side of  $\alpha$ , but this configuration would be covered by Case I or II. So we may assume  $D \cup D'$  is trivial, and Case III is finished.  $\square$

Now we can prove a converse to Proposition 1.6:

**Theorem 3.15.** *If  $\tilde{M} \rightarrow M$  is a covering space with  $M$  irreducible and orientable, then  $\tilde{M}$  is irreducible.*

**Proof:** This follows quite closely the scheme of proof of the Sphere Theorem. The main thing to observe is that Lemmas 3.13 and 3.14 remain valid if ‘triviality’ for embedded spheres is redefined to mean ‘bounding a ball.’ The two properties of trivial spheres which were used were: (1) Surgery on a nontrivial sphere cannot produce two trivial spheres, and (2) Triviality is invariant under isotopy.

Suppose  $\tilde{M}$  is reducible, hence contains a nontrivial sphere  $S_0$ . The proof of the Sphere Theorem gives a new nontrivial sphere  $S \subset \tilde{M}$  which covers either a sphere or an  $\mathbb{R}P^2$  in  $M$ . In the latter case the  $\mathbb{R}P^2$  is 1-sided since we assume  $M$  orientable, and an  $I$ -bundle neighborhood of this  $\mathbb{R}P^2$  is  $\mathbb{R}P^3$  minus a ball, so irreducibility of  $M$  implies  $M = \mathbb{R}P^3$ , hence  $\tilde{M} = S^3$ , which is irreducible, a contradiction. In case the sphere  $S \subset \tilde{M}$  covers a sphere in  $M$ , the latter sphere bounds a ball in  $M$ , which lifts to a ball in  $\tilde{M}$  bounded by  $S$ , a contradiction again.  $\square$

Recall the example  $S^1 \times S^2 \rightarrow S^1 \times \mathbb{R}P^2$  of a covering of an irreducible manifold by a reducible manifold, which shows the necessity of the orientability hypothesis in Theorem 3.15. To extend the theorem to the nonorientable case one needs to restrict  $M$  to be  $P^2$ -irreducible, that is, irreducible and containing no 2-sided  $\mathbb{R}P^2$ 's.

### Exercises

1. Show that a closed connected 3-manifold with  $\pi_1$  free is a connected sum of  $S^1 \times S^2$ 's,  $S^1 \tilde{\times} S^2$ 's, and possibly a homotopy sphere.
2. Extend Proposition 3.4 to the nonorientable case.
3. Show that every closed surface of even Euler characteristic is the boundary of some compact 3-manifold.
4. Show that if  $M$  is simply-connected, then every circle in  $\partial M$  separates  $\partial M$ . In particular, components of  $\partial M$  which are closed must be spheres.
