Abstract

Theorems of hyperarithmetic analysis (THAs) occupy an unusual neighborhood in the realms of reverse mathematics and recursion-theoretic complexity. They lie above all the fixed (recursive) iterations of the Turing jump but below ATR_0 (and so \(\Pi^1_1\)-CA_0 or the hyperjump). There is a long history of proof-theoretic principles which are THAs. Until the papers reported on in this communication, there was only one mathematical example. Barnes, Goh and Shore [ta] analyzes an array of ubiquity theorems in graph theory descended from Halin’s [1965] work on rays in graphs. They seem to be typical applications of ACA_0 but are actually THAs. These results answer Question 30 of Montalbán’s Open Questions in Reverse Mathematics [2011] and supply several other natural principles of different and unusual levels of complexity.

This work led in Shore [ta] to a new neighborhood of the reverse mathematical zoo: almost theorems of hyperarithmetic analysis (ATHAs). When combined with ACA_0 they are THAs but on their own are very weak. Denizens both mathematical and logical are provided. Generalizations of several conservativity classes (\(\Pi^1_1\), r-\(\Pi^1_1\) and Tanaka) are defined and these ATHAs as well as many other principles are shown to be conservative over RCA_0 in all these senses and weak in other recursion-theoretic ways as well. These results answer a question raised by Hirschfeldt and

*All the authors were partially supported by NSF Grant DMS-1161175.
reported in Montalbán [2011] by providing a long list of pairs of principles one of which is very weak over RCA\textsubscript{0} but over ACA\textsubscript{0} is equivalent to the other which may be strong (THA) or very strong going up a standard hierarchy and at the end being stronger than full second-order arithmetic.

1 Introduction

There are now (at least) two widespread approaches to analyzing the complexity of mathematical theorems and logical (axiomatic) systems. One is computational (recursion-theoretic) and the other is proof-theoretic. They give rise to closely related measures and hierarchies of complexity. The first grows out of recursive, computable or constructive mathematics. Typically, we have a theorem asserting that for every object $X$ of some kind there is another $Y$ with specified properties. In this setting, the question one answers is how difficult (given $X$) is it to construct $Y$? The measuring rods for difficulty here are most often marked by levels of complexity with respect to computability in the sense of Turing (degrees). The second, embodied in what is now known as reverse mathematics, attempts to say how hard is it to prove the theorem. Here the measuring rods are generally axiomatic subsystems of second-order arithmetic sufficient to carry out a proof. (The standard proof-theoretically oriented text here is Simpson [2009]. Hirschfeldt [2014] gives a good view from computability theory.)

The two approaches are closely related and roughly share five basic levels of complexity that, for the first several decades of each of the two views, seemed to characterize almost all theorems of classical mathematics. Proof-theoretically, the first is a weak system of second-order arithmetic, RCA\textsubscript{0} which, in addition to the basic axioms about $+$, $\times$ and $<$, contains comprehension axioms for $\Delta^0_1$ sets and induction for $\Sigma^0_1$ formulas. Computationally, this corresponds to classical computable (recursive) mathematics. The other four levels are determined by adding on stronger existence/comprehension axioms. WKL\textsubscript{0} asserts that every infinite subtree of $2^{<\mathbb{N}}$, the tree of finite sequences of 0s and 1s, has an (infinite) branch. The next level is ACA\textsubscript{0} which adds comprehension axioms for arithmetic formulas or, equivalently, requires closure under (finite iterations of) the Turing jump. The fourth level, ATR\textsubscript{0}, extends comprehension to include transfinite iterations of arithmetic comprehension. This roughly corresponds to the transfinite iterations of the Turing jump through the recursive ordinals, i.e. the hyperarithmetic sets. The last of the basic systems is $\Pi^1_1$-CA\textsubscript{0} which includes comprehension for $\Pi^1_1$ formulas. This corresponds to Kleene’s hyperjump in terms of computational strength.

Over the past couple of decades the earlier pattern of results has been broken by a large number of constructions/theorems which are provably different from each of these “big five” systems and have unusual computational strength. They are now often called the “zoo” of reverse mathematics. (For pictures, see https://rmzoo.math.uconn.edu/diagrams/.) For ordinary theorems of classical mathematics, the large majority of these examples have been weaker than ACA\textsubscript{0} and so constructions recursive in a finite number of iterations
of the Turing jump.

In this communication reporting on the results in Barnes, Goh and Shore [ta], Goh [ta] and Shore [ta], we discuss two related classes of mathematical theorems and logical principles that occupy neighborhoods of the reverse mathematical zoo that have had very few other denizens. They all fall outside of the big five and none are provable from ACA\textsubscript{0}. The first consists of what are called THAs, theorems (or theories) \( T \) of hyperarithmetical analysis (Definition 2.13). Computationally, these lie above each fixed transfinite (recursive) iteration of arithmetic comprehension but do not (proof-theoretically) imply ATR\textsubscript{0}. While some of the THAs we study are proof-theoretically strictly weaker than ATR\textsubscript{0}, some are incomparable with it. Indeed, while there is a precise recursion-theoretic characterization of THAs (Definition 2.13), there can be no proof-theoretic one at least not in first-order logic. (See Van Wesep [1977, 2.2.2] and also Montalbán [2006, remarks after Definition 1.1].)

The study of such systems began with the work of Kreisel [1962], H. Friedman [1967], [1971], [1975], Steel [1978] and others in the 1960s and 1970s and continued into the last decades (as in Montalbán [2006], [2008], Neeman [2008], [2011] and others). Several axiomatic systems and logical theorems were found to be THAs and proven to lie in a number of distinct classes in terms of proof-theoretic complexity. Until now, however, there has been only one mathematical but not logical example, i.e. one not mentioning classes of first-order formulas or their syntactic complexity. This was a result (INDEC) about indecomposability of linear orderings in Jullien’s [1968] thesis (see Rosenstein [1982, Lemma 10.3]). It was shown to be a THA by Montalbán [2006] and further investigated in Neeman [2008] and [2011].

The natural question, raised explicitly in Montalbán’s “Open Questions in Reverse Mathematics” [2011, Q. 30], was are there any others? The answer is provided by Barnes, Goh and Shore [ta]. There is a whole family of theorems from graph-theoretic combinatorics that are THAs. The examples are primarily variations on some classical theorems of Halin [1965] and [1970] and related results in what is now called ubiquity theory. (See Diestel [2017, Ch. 8] for a contemporary treatment.)

The archetypical example here is what we call the Infinite Ray Theorem (IRT) from Halin [1965]. In more contemporary terminology, it says that any graph \( G \) which contains, for each \( n \), a sequence \( \langle R_0, \ldots, R_{n-1} \rangle \) of disjoint rays (a ray is a sequence \( \langle x_i | i \in N \rangle \) of distinct vertices such that there is an edge between each \( x_i \) and \( x_{i+1} \)) also contains an infinite such sequence of rays. On its face, this sounds like a compactness theorem and so should be provable in WKL\textsubscript{0} or ACA\textsubscript{0}. Indeed, the construction of Andreae in Diestel [2017 8.2.5(i)] of the desired sequence of rays proceeds by a recursion through the natural numbers in which each step is arithmetical and so looks like a typical application of ACA\textsubscript{0}. We prove that it and several variations are much more complicated and indeed THAs. One collection of variations consists of consequences of a restricted version of Choice, \( \Sigma^1_1\text{-AC}_0 \) which is well known to be a THA (essentially Kreisel [1962]). The proofs that they are themselves THAs is recursion-theoretic. The analysis here led us
to some related results and even a new logical system given by a restricted version of \( \Sigma^1_1-\text{AC}_0 \) (Definition 3.13) which is also a THA. We show by proof-theoretic arguments that another collection of variants of a version in Halin [1965] requiring one type of maximality of the constructed sequence which are also THAs cannot be proven in \( \Sigma^1_1-\text{AC}_0 \) because each of them implies more induction than is available there. Indeed, some go beyond what is provable even in \( \text{ATR}_0 \). Finally we show that each of another class of variations mentioned in Halin [1965] that requires a different type of maximality is both proof-theoretically and computationally stronger than \( \text{ATR}_0 \). Each is equivalent to \( \Pi^1_1-\text{CA}_0 \) and so to closure under the hyperjump.

We present these results in §3 and discuss some relations among the variations from the perspective of reverse mathematics. Almost all of these results are from Barnes, Goh and Shore [ta]. The technically most difficult ones that use Steel forcing to place some of these theorems (and logical systems) among the previously studied THAs with respect to proof-theoretic strength are in Goh [ta].

The second group of mathematical theorems and logical principles \( T \) that we study contains ones that, from the pure proof-theoretic point of view, are very weak. More precisely they are conservative over \( \text{RCA}_0 \) for a wide range of classes \( \Gamma \) of sentences. (That is, for any \( \varphi \in \Gamma \), if \( \text{RCA}_0 + T \vdash \varphi \) then \( \text{RCA}_0 \vdash \varphi \).) The classes \( \Gamma \) that we consider include new generalizations of the well studied one \( \Pi^1_1 \) and of three less studied ones, \( r-\Pi^2_1 \) (Hirschfeldt, Shore and Slaman [2009]) and what we call Tanaka formulas and \( r \)-Tanaka formulas after a conjecture of Tanaka’s about the conservativity of \( \text{WKL}_0 \) over \( \text{RCA}_0 \) proven in Simpson, Tanaka and Yamazaki [2002]. (See Definition 4.2.) So, in particular, none of these principles prove \( \text{ACA}_0 \). On the other hand, what makes them unusual is that they each become very strong once we add \( \text{ACA}_0 \). Many of them become THAs and these we call, ATHAs, almost theorems (theories) of hyperarithmetic analysis (Definition 2.14). These include both mathematical theorems related to the variants of Halin’s theorem and of familiar logical systems. Another collection of them form hierarchies whose members (over \( \text{ACA}_0 \)) prove \( \Pi^n_{1}-\text{CA}_0 \) with \( n \) running through the natural numbers as we go up the hierarchies. At the end of these hierarchies we have principles with all these conservation properties over \( \text{RCA}_0 \) which are stronger than full second-order arithmetic over \( \text{ACA}_0 \). These results are from Shore [ta].

The proofs of all of these conservativity results proceed by defining some very general classes of forcings and showing that any sentence of the desired class \( \Gamma \) that can be made true in an extension of a given model of \( \text{RCA}_0 \) by iterating forcings from these classes must already be true in the given model. These notions of forcing include many well known ones such as Cohen, Laver, Mathias, Sacks and Silver forcing and many variations as well as special purpose ones introduced for specific applications to mathematical theorems related to our graph-theoretic theorems. Thus we strengthen many well known conservativity results as well as proving new ones. The proofs (also from Shore [ta]) that many of these theorems are very strong over \( \text{ACA}_0 \) are specific to the particular results but are usually not difficult. We view these results together as answering another question raised in Montalbán [2011, 6.1.1]. Attributing the question to Hirschfeldt, Mont-
talbán points out that there are very few examples where natural equivalences are known
to hold over strong theories but not over RCA$_0$ particularly if one excludes the cases
where the only additional axioms needed are forms of induction. Hirschfeldt asked for
more such examples. This work provides a whole array of pairs of distinct principles with
a wide range of strength which are pairwise equivalent over ACA$_0$ but not over RCA$_0$.
Thus they provide evidence that in some settings it would make sense to take ACA$_0$
as the base theory for reverse mathematical investigations rather than RCA$_0$.

2 Basic Notions and Background

2.1 Subsystems of Second-Order Arithmetic

Formally, we are working in models $\mathcal{N} = (N, S(N), +, \times, \leq, \in, 0, 1)$ of second-order arith-
metic. The first-order quantifiers range over $N$. The second-order ones over $S(N)$ which
is a collection of subsets of $N$. The function, relations and constants are taken to
have the usual basic elementary properties. We generally abbreviate these structures
as $\mathcal{N} = (N, S(N))$. We are interested in ones which are models at least of RCA$_0$. The
standard models are those where $N$ is $\mathbb{N}$ (the true natural numbers) and the remain-
ing symbols have their standard interpretations. When we define semantics or forcing
we expand the formal language to include constants for each element of $N$ and $S(N)$
and possibly some recursive (i.e. $\Delta^0_1$) predicates. Unless otherwise specified, all sets and
structures we consider are countable.

The standard text here is Simpson [2009] to which we refer for formal details of
syntax and terminology including the definitions of the basic axiom systems of reverse
mathematics. The major standard axiomatic principles other than the five discussed in
§1 that we need are variations on choice principles:

Definition 2.1. $\Sigma^1_n$-AC is the principle $\forall A[\forall n \exists X \Phi(A, n, X) \rightarrow \exists Y \forall n \Phi(A, n, Y^n)]$ for
every $\Sigma^1_n$ formula $\Phi$ with free set variables $A$ and $X$. In general, if $Q$ is a principle such
as this one we denote the axiomatic system RCA$_0 + Q$ by $Q_0$.

2.2 Graph-Theoretic Notions

We take Diestel [2017] as our basic reference for graph theory but at times provide
versions of definitions which are clearly classically equivalent to the standard ones but
are better suited to reverse mathematics or complexity calculations.

Definition 2.2. A graph $H$ is a pair $\langle V, E \rangle$ consisting of a set $V$ (of vertices) and a set
$E$ of unordered pairs $\{u, v\}$ with $u \neq v$ from $V$ (called edges). These structures are also
called undirected graphs (or here $U$-graphs). A structure $H$ of the form $\langle V, E \rangle$ as above
is a directed graph (or here $D$-graph) if $E$ consists of ordered pairs $\langle u, v \rangle$ of vertices with
$u \neq v$. To handle both cases simultaneously, we often use $X$ to stand for undirected (U)
or directed (D). We then use \( (u, v) \) to stand for the appropriate kind of edge, i.e. \( \{u, v\} \) or \( (u, v) \).

**Definition 2.3.** An X-subgraph of the X-graph \( H \) is an X-graph \( H' = (V', E') \) such that \( V' \subseteq V \) and \( E' \subseteq E \).

**Definition 2.4.** An X-ray in \( H \) is a pair consisting of an X-subgraph \( H' = (V', E') \) of \( H \) and an isomorphism \( f_{H'} \) from \( N \) with edges \( (n, n + 1) \) for \( n \in N \) to \( H' \). We say that the ray begins at \( f(0) \). We also describe this situation by saying that \( H \) contains the X-ray \( \langle H', f_{H'} \rangle \). We sometimes abuse notation by saying that the sequence \( \langle f(n) \rangle \) of vertices is an X-ray in \( H \). Similarly we consider double X-rays where the isomorphism \( f_{H'} \) is from the graph on \( \{ (n, 0), (n, 1) \, | \, n \in N \} \) with edges \( \{ (0, 0), (1, 0) \}, \{ (n + 1, 0), (n, 0) \} \) and \( \{ (n, 1), (n + 1, 1) \} \) for \( n \in N \), i.e. up to isomorphism the graph of the usual order relation on the integers. We use Z-ray to stand for either a (single) ray \( (Z = S) \) or double ray \( (Z = D) \) and so we have, in general, Z-X-rays or just Z-rays if the type of graph \( (U \) or \( D) \) is already established.

An X-path \( P \) in an X-graph \( H \) is defined similarly to single rays except that the domain of \( f_P \) is a proper initial segment of \( N \) instead of \( N \) itself.

**Definition 2.5.** \( H \) contains \( k \) many Z-X-rays for \( k \in N \) if there is a sequence \( \langle H_i, f_i \rangle_{i < k} \) such that each \( \langle H_i, f_i \rangle \) is a Z-X-ray in \( H \) (with \( H_1 = (V_1, E_1) \)).

\( H \) contains \( k \) many disjoint (or vertex-disjoint) Z-X-rays if the \( V_i \) are pairwise disjoint. \( H \) contains \( k \) many edge-disjoint Z-X-rays if the \( E_i \) are pairwise disjoint. We often use \( Y \) to stand for either vertex \( (V) \) or edge \( (E) \) as in the following definitions.

An X-graph \( H \) contains arbitrarily many Y-disjoint Z-X-rays if it contains \( k \) many such rays for each \( k \in N \).

An X-graph \( H \) contains infinitely many Y-disjoint Z-X-rays if there is an X-subgraph \( H' = (V', E') \) of \( H \) and a sequence \( \langle H_i, f_i \rangle_{i \in N} \) such that each \( \langle H_i, f_i \rangle \) is a Z-X-ray in \( H \) (with \( H_1 = (V_1, E_1) \)) such that the \( V_i \) or \( E_i \), respectively for \( Y = V, E \), are pairwise disjoint and \( V' = \cup V_i \) and \( E' = \cup E_i \).

The starting point of the work in Barnes, Goh and Shore [ta] is a theorem of Halin [1965] that we call the infinite ray theorem as expressed in Diestel [2017].

**Definition 2.6 (Halin’s Theorem).** IRT, the infinite ray theorem: Every graph \( H \) which contains arbitrarily many disjoint rays contains infinitely many.

We consider versions IRT\(_{XYZ} \) of this theorem which allow \( H \) to be an undirected \( (X = U) \) or a directed \( (X = D) \) graph and for the disjointness requirement to be vertex \( (Y = V) \) or edge \( (Y = E) \). We also allow the rays to be single \( (Z = S) \) or double \( (Z = D) \) and consider restrictions of some of these theorems to specific families of graphs. In particular, we begin with trees. Note that we define trees as a class of graphs and so use in our basic language for our definitions the edge relation but not the induced partial
order. This causes some conflict between the standard graph-theoretic terminology above and some common set-theoretic terminology. For example, a path in a tree (viewed as a graph) need not start at the root of the tree or be linearly ordered in the induced partial order on the tree. We define the branches of a tree so that they are actually the maximal linearly ordered sets in the tree with respect to the usual induced ordering as is fairly common in set-theoretic terminology.

Definition 2.7. A tree is a graph $T$ with a designated element $r$ called its root such that for each vertex $v \neq r$ there is a unique path from $r$ to $v$. A branch in $T$ is a ray that begins at its root. We denote the set of its branches by $[T]$ and say that $T$ is well-founded if $[T] = \emptyset$ and otherwise it is ill-founded. A forest is an effective disjoint union of trees, or more formally, a graph with a designated set $R$ (of vertices called roots) such that for each vertex $v$ there is a unique $r \in R$ such that there is a path from $r$ to $v$ and, moreover, there is only one such path. In general, the effectiveness we assume when we take disjoint unions of graphs means that we can effectively (i.e. computably) identify each vertex in the union with the original vertex (and the graph to which it belongs) which it represents in the disjoint union.

Definition 2.8. A directed tree is a directed graph $T = \langle V, E \rangle$ such that its underlying graph $\hat{T} = \langle V, \hat{E} \rangle$ where $\hat{E} = \{\{u, v\} | \langle u, v \rangle \in E \lor \langle v, u \rangle \in E\}$ is a tree. A directed forest is a directed graph whose underlying graph is a forest.

Definition 2.9. An $X$-graph $H$ is locally finite if, for each $u \in V$, the set $\{v \in E | \langle u, v \rangle \in E \lor \langle v, u \rangle \in E\}$ of neighbors of $u$ is finite.

2.3 The Hyperarithmetic Hierarchy

We assume familiarity with the basic notion of relative complexity of sets and functions as given by Turing reducibility, $X \leq_T Y$, and the Turing jump operator, $X'$, and refer to any standard text such as Rogers [1987]. Iterating the jump into the transfinite brings us to hyperarithmetic theory. Here, the now standard text is Sacks [1990].

Definition 2.10. We represent ordinals $\alpha$ as well-ordered relations on $\mathbb{N}$. Typically such ordinal notations are endowed with various additional structure such as identifying $0$, successor and limit ordinals and specifying cofinal $\omega$-sequences for the limit ordinals.

An ordinal is recursive (in a set $X$) if it has a recursive (in $X$) representation. For a set $X$ and ordinal (notation) $\alpha$ recursive in $X$, we define the transfinite iterations $X^{(\alpha)}$ of the Turing jump of $X$ by induction: $X^{(0)} = X$; $X^{(\alpha+1)} = (X^{(\alpha)})'$ and for a limit ordinal $\lambda$, $X^{(\lambda)} = \oplus\{X^{(\alpha)} | \alpha < \lambda\}$ (or as the sum over the $X^{(\alpha)}$ in the specified cofinal sequence).

Definition 2.11. $HYP(X)$, the collection of all sets hyperarithmetic in $X$ consists of those sets recursive in some $X^{(\alpha)}$ for $\alpha$ an ordinal recursive in $X$. These are also the sets $\Delta^1_1$ in $X$. 

7
Above all the sets hyperarithmetic in \( X \) lies its hyperjump.

**Definition 2.12.** The *hyperjump of* \( X \), \( \mathcal{O}^X \), is the set \( \{ e | \Phi^X_e \text{ is (the characteristic function of) a well-founded subtree of } N^{<N} \} \).

We can now define the primary objects of our analysis. Note that the definitions only refer to standard models.

**Definition 2.13.** A sentence (theory) \( T \) is a *theorem (theory) of hyperarithmetic analysis (THA)* if

1. For every \( X \subseteq \mathbb{N} \), \( (\mathbb{N}, \text{HYP}(X)) \models T \) and
2. For every \( S \subseteq 2^{\mathbb{N}} \), if \( (\mathbb{N}, S) \models T \) and \( X \in S \) then \( \text{HYP}(X) \subseteq S \).

**Definition 2.14.** A theorem or theory \( T \) is an *almost theorem (theory) of hyperarithmetic analysis (ATHA)*, if \( T \not
equiv \text{ACA}_0 \) but \( T + \text{ACA}_0 \) is a THA.

## 3 IRT\(_{XYZ}\) and Hyperarithmetic Analysis

We analyze the strength of the variations IRT\(_{XYZ}\) of Halin’s theorem. Classically, IRT\(_{UVS}\) and IRT\(_{UVD}\) were proved by Halin [1965] and [1970]. IRT\(_{UES}\) is an exercise in Diestel [2017, 8.2.5(ii)] while IRT\(_{DVS}\) and IRT\(_{DES}\) may be folklore. We prove that all of these are THAs. Of the other three variants, IRT\(_{DED}\) and IRT\(_{DVD}\) are open problems of graph theory (Bowler, Carmesin and Pott [2015] and Bowler [personal communication]). We do, however, have interesting and unusual results about these principles when restricted to directed forests. The remaining variant, IRT\(_{UED}\), was proved by Bowler, Carmesin and Pott [2015] using structural results about the topological notion of ends in graphs. All the results in this section not otherwise attributed are from Barnes, Goh and Shore [ta].

We first note some reverse mathematical relations among these principles.

**Theorem 3.1** (RCA\(_0\)). i) IRT\(_{DED}\) \( \rightarrow \) IRT\(_{DVD}\), IRT\(_{UED}\), IRT\(_{DES}\).

ii) IRT\(_{DVD}\) \( \rightarrow \) IRT\(_{UVD}\), IRT\(_{DVS}\).

iii) IRT\(_{DES}\) \( \rightarrow \) IRT\(_{DVS}\), IRT\(_{UES}\).

iv) IRT\(_{DVS}\) \( \rightarrow \) IRT\(_{UVS}\).

The proofs of these implications are purely combinatorial and all follow the same basic plan. To deduce IRT\(_{XYZ}\) from IRT\(_{X'Y'Z'}\), we provide computable maps \( g, h \) and \( k \) which take \( X\)-graphs \( G \) to \( X'\)-graphs \( G' \), \( Y\)-disjoint \( Z\)-rays or sets of \( Y\)-disjoint \( Z\)-rays in \( G \) to \( Y'\)-disjoint \( Z'\)-rays or sets of \( Y'\)-disjoint \( Z'\)-rays in \( G' \), and \( Y'\)-disjoint \( Z'\)-rays or sets of \( Y'\)-disjoint \( Z'\)-rays in \( G' \) to \( Y\)-disjoint \( Z\)-rays or sets of \( Y\)-disjoint \( Z\)-rays in \( G \), respectively. These functions are designed to take witnesses of the hypothesis of IRT\(_{XYZ}\) in \( G \) to witnesses of the hypothesis of IRT\(_{X'Y'Z'}\) in \( G' \) and witnesses to the conclusion
of IRTXYZ in G′ to witnesses to the conclusion of IRTXYZ in G. Clearly it suffices to provide such computable maps to establish the desired reduction in RCA0. We use these reductions to prove one of our major results: all of the IRTXYZ have strength at least that of some THAs and that most are, in fact, themselves THAs. We discuss two other reductions not in RCA0 in Theorem 3.10 and §4.

**Theorem 3.2.** All single-ray variants of IRT (i.e. IRTXYS) and IRTUVD are theorems of hyperarithmetic analysis.

The proofs have two parts. One is recursion-theoretic. It first provides a coding into computable graphs that have arbitrarily many disjoint rays such that any sequence of infinitely many disjoint rays computes 0′. Thus each of the principles imply ACA0. Then we prove that, if 0(α) exists for each α < λ (recursive ordinals), then 0(λ) exists. The method here is to use known facts of hyperarithmetic theory to construct a sequence of trees each of which has exactly one branch uniformly of degree 0(α) (or variations appropriate to the version of IRT being considered) and apply the version of IRT to get a sequence of these branches cofinal in λ and so construct 0(λ). This guarantees that the second clause of the definition of THA (2.13) is satisfied.

The second part consists of showing that each of these versions of IRT are provable from the THA Σ11-AC0. Thus the IRT variants satisfy the first clause as well. The proofs of the variants in Σ11-AC0 are mostly careful analyses of standard proofs or variations on such. The basic constructions are recursions which at each step perform arithmetic operations on given or constructed graphs and apply Menger’s theorem for finite graphs.

The construction for IRTDES requires some additional ideas that include using line graphs to move from edge disjointness to vertex disjointness and a reduction to locally finite graphs similar to an analysis in Bowler, Carmesin and Pott [2015] that we discuss in §4.

What prevents the construction from being one in ACA0 is the need to apply the hypothesis of IRT at step n to be able to use a sequence Rn = ⟨Rni| i < f(n)⟩ of disjoint rays of length f(n) for some specified recursive function f. While the hypothesis tells us there is such a sequence for each n, producing the whole sequence ⟨Rn⟩ to start the constructions formally seems to use some form of choice (Σ11-AC clearly suffices). This preliminary step is the essential source of the complexity of the IRTXYZ. Indeed, we show that, each IRTXYS and IRTUVD is equivalent (over RCA0) to the principle that its hypothesis implies the existence of a sequence ⟨Rn⟩ as just described.

**Definition 3.3.** SCRXYZ: For every X-graph G with arbitrarily many Y-disjoint Z-rays, there is a sequence ⟨Rn⟩ such that each Rn is a sequence of n many Y-disjoint Z-rays.

We now turn to two other types of variations on IRT that involve notions of maximality. The first actually follows the original formulation of IRT in Halin [1965].

**Definition 3.4.** IRT∗XYZ: Every X-graph G has a set of Y-disjoint Z-rays of maximum cardinality.
It is easy to see that the difference between $\text{IRT}_{XYZ}^*$ and $\text{IRT}_{XYZ}$ is just an induction argument. It suffices to have $\Sigma^1_1$, induction for $\Sigma^1_1$ (rather than $\Sigma^0_1$) formulas.

**Proposition 3.5.** For each choice of $XYZ$, $\text{IRT}_{XYZ}^*$ implies $\text{IRT}_{XYZ}$ over $\text{RCA}_0$ and $\text{IRT}_{XYZ}$ implies $\text{IRT}_{XYZ}^*$ over $\text{RCA}_0 + \Sigma^1_1$. Therefore $\text{IRT}_{XYZ}$ and $\text{IRT}_{XYZ}^*$ are equivalent over $\text{RCA}_0 + \Sigma^1_1$.

As a theory being a THA depends only on its standard models (in which full induction holds), we see that we have another collection of THAs from the literature.

**Theorem 3.6.** For all the $\text{IRT}_{XYS}$ and $\text{IRT}_{UVD}$ (which are THAs by Theorem 3.2), the $\text{IRT}_{XY}^*$ are also THAs.

Moreover, we can show that these $\text{IRT}_{XYZ}^*$ are proof-theoretically strictly stronger than the corresponding $\text{IRT}_{XYZ}$ and indeed not even provable from $\Sigma^1_1-$AC$_0$.

**Theorem 3.7.** For each choice of $XYZ$, $\text{IRT}_{XYZ}^*$ implies $\text{ACA}^*_0$ and so proves the consistency of $\Sigma^1_1-$AC$_0$. Thus none is provable in $\Sigma^1_1-$AC$_0$. In particular $\text{IRT}_{XYS}$ and $\text{IRT}_{UVD}$ are each strictly weaker than the corresponding $\text{IRT}_{XYZ}$.

Here $\text{ACA}^*_0$ is the known principle adding the instance of induction giving all finite iterations of the jump: $(\forall A)(\forall n)(\exists W)(W[0] = A \land (\forall i < n)(W[i+1] = W[i]'))$. The proof of Theorem 3.7 shows first that $\text{ACA}^*_0$ follows from each $\text{IRT}_{XYZ}^*$ by using Simpson [2009, V.5.4] and then examines his argument for IX.4.6 to get the consistency result.

We can do more for special cases of the open questions $\text{IRT}_{DED}$ and $\text{IRT}_{DVD}$. Indeed, we have that restricting these principles to various classes of graphs supply new THAs which are strictly stronger than $\Sigma^1_1-$AC$_0$ and not provable even in ATR$_0$. 

**Theorem 3.8.** Each of $\text{IRT}_{DVD}^*$ restricted to directed forests is a THA which strictly implies $\Sigma^1_1-$AC$_0$ over $\text{RCA}_0$ but is not provable in ATR$_0$.

More generally, we can precisely characterize the reverse mathematical strength of all these variants.

**Theorem 3.9.** The following are equivalent (over $\text{RCA}_0$):
1. $\Sigma^1_1-$AC$_0 + \Sigma^1_1$.
2. $\text{IRT}_{DED}$ for directed forests + $\Sigma^1_1$.
3. $\text{IRT}_{DED}^*$ for directed forests.
4. $\text{IRT}_{DVD}$ for directed forests.
5. $\text{IRT}_{DVD}^*$ for directed forests + $\Sigma^1_1$.

The proofs here use a new combinatorial argument to show that $\Sigma^1_1-$AC$_0$ implies $\text{IRT}_{DED}$ for directed forests, a short coding to derive $\Sigma^1_1-$AC from $\text{IRT}_{DVD}^*$ and another one to show that $\text{IRT}_{DVD}^*$ implies $\Sigma^1_1$ as well as several previously established implications.
As $\Sigma^1_1$ is not provable in ATR$^0$ by Simpson [2009, IX.4.7], we have a lower bound for IRT$^*_{DYD}$.

More difficult combinatorial arguments show that if we consider IRT$^*_{UVD}$ over RCA$^0$ and so IRT$^*_{UVD}$ over RCA$^0 + \Sigma^1_1$ we can derive a reduction not implied by those of Theorem 3.1 and the immediate ones of Proposition 3.5.

**Theorem 3.10.** IRT$^*_{UVD}$ implies IRT$^*_{UVS}$ over RCA$^0$. Therefore (1) IRT$^*_{UVD}$ implies IRT$^*_{UVS}$ over RCA$^0 + \Sigma^1_1$; and (2) if any standard model of RCA$^0$ satisfies IRT$^*_{UVD}$, then it satisfies IRT$^*_{UVS}$ as well.

We now turn to the second notion of maximality for IRT variants. Instead of asking for sets of disjoint rays of maximal cardinality we ask for ones that are maximal in the sense of containment. Of course, the existence of such sets follows immediately from Zorn’s Lemma and was so noted in Halin [1965]. In terms of computational and reverse mathematical strength, they are much stronger than the IRT or IRT$^*$ versions.

**Definition 3.11.** MIRT$^*_{XYZ}$: Every X-graph G has a (possibly finite) sequence $(R_i)_i$ of Y-disjoint Z-rays which is maximal, i.e. for any Z-ray $R$ in G, there is some $i$ such that $R$ and $R_i$ are not Y-disjoint.

**Theorem 3.12.** Each MIRT$^*_{XYZ}$ is equivalent to $\Pi^1_1$-CA$^0$ over RCA$^0$.

We close this section with a summary of the relations between the THAs introduced here along with another new one that they suggested and others already studied in the literature. Many of our results are displayed in Figure 1.

As mentioned in §1, the only previously known purely mathematical THA was INDEC. There were also one or two quasi-mathematical ones which, like ABW, are versions of standard principles such as the Bolzano-Weierstrass theorem but restricted to arithmetic sets of reals. (See Friedman [1975] and Conidis [2012].) All the others were typical logical axioms or theorems. The standard examples include $\Sigma^1_1$-DC$^0$, $\Sigma^1_1$-AC$^0$, $\Delta^1_1$-CA$^0$ as well as $\Pi^1_1$-SEP and weak-$\Sigma^1_1$-AC$^0$. The known relationships among these systems were as follows: $\Sigma^1_1$-DC$^0 \rightarrow \Sigma^1_1$-AC$^0 \rightarrow \Pi^1_1$-SEP $\rightarrow \Delta^1_1$-CA$^0 \rightarrow$ INDEC$^0$; $\Delta^1_1$-CA$^0 \rightarrow$ weak-$\Sigma^1_1$-AC$^0$; INDEC$^0 + \Sigma^1_1 \rightarrow$ weak-$\Sigma^1_1$-AC$^0$; $\Sigma^1_1$-AC$^0 + \Sigma^1_1 \rightarrow$ ABW$^0 + \Sigma^1_1 \rightarrow$ weak-$\Sigma^1_1$-AC$^0$ and $\Delta^1_1$-CA$^0 \not\rightarrow$ ABW$^0 \not\rightarrow$ INDEC$^0$. We use $\Rightarrow$ to denote strict implication between theories. (See Simpson [2009], Montalbán [2006], [2008], Neeman [2008], [2011] and Conidis [2012] for definitions, proofs and references.)

We have already provided many relations between $\Sigma^1_1$-AC$^0$ and IRT$^*_{XYZ}$ and IRT$_{XYZ}$. Our first step in providing consequences of the IRT$^*_{XYZ}$ or IRT$_{XYZ}$ which we know are implied by $\Sigma^1_1$-AC$^0 + \Sigma^1_1$ or $\Sigma^1_1$-AC$^0$, respectively was that weak-$\Sigma^1_1$-AC$^0$ follows from IRT + $\Sigma^1_1$. This proof led us to an apparent strengthening of weak-$\Sigma^1_1$-AC$^0$ which was also a consequence of each IRT$^*_{XYZ}$.

**Definition 3.13.** The principle finite-$\Sigma^1_1$-AC asserts that, for every arithmetic $\Phi(A, n, X)$,

$$\forall A[(\forall n)(\exists \text{ nonzero finitely many } X) \Phi(A, n, X) \rightarrow \exists Y \forall n \Phi(A, n, Y^{[n]})].$$
Figure 1: Partial zoo involving known axiom systems and some IRT variants. Single arrows denote implication over RCA\(_0\) while double arrows denote strict implication over RCA\(_0\). All theories are THA except for MIRT, \(\Pi^1_1\)-CA\(_0\), ATR\(_0\) and ACA\(_0\): For the IRT variants see Theorems 3.2, 3.6; otherwise see Montalbán [2006]. For readability we have not displayed all variants of IRT and IRT*\(_*\). Most of the results in the figure are proved for some other IRT\(_{XYZ}\) as well (or IRT*\(_{XYZ}\), as appropriate) except for (4). The unlabeled implications and nonimplications along and to the right of the vertical axis from \(\Pi^1_1\)-CA\(_0\) to ACA\(_0\) are well-known (see Simpson [2009], in particular Corollary IX.4.7.) (1): These are proved in Goh [ta]. The implications from \(\Sigma^1_1\)-AC\(_0\) to IRT\(_{DES}\) and IRT\(_{UVD}\) follow from our proof of Theorem 3.2 (see the second paragraph after Theorem 3.2). The implications from \(\Sigma^1_1\)-AC\(_0\) to IRT*\(_{DES}\) and IRT*\(_{UVD}\) follow from the above and Proposition 3.5. The strict implications from IRT*\(_{XYZ}\) to IRT*\(_{XYZ}\) hold by Proposition 3.5 and Theorem 3.7. (2): Theorems 3.14 and 3.7. (3): Theorem 3.1. (4): Theorem 3.10. (5) follow from our proof of Theorem 3.2 (see the first paragraph after Theorem 3.2) (6): Theorem 3.12. (7): Theorem 3.9. (the subscript DF indicates that we restrict IRT*\(_{DED}\) to directed forests.)
Here we have weakened the usual hypothesis of weak-$\Sigma^1_1$-$\text{AC}_0$ from asserting that for each $n$ there is precisely one $X$ such that $A(n, X)$ to there being a finite sequence containing all such $X$. So, of course, finite-$\Sigma^1_1$-$\text{AC}_0$ implies weak-$\Sigma^1_1$-$\text{AC}_0$. We provide many other relations as well.

**Theorem 3.14.** IRT$_{XYZ}^*$ implies finite-$\Sigma^1_1$-$\text{AC}_0$ over RCA$_0$. So IRT$_{XYZ}$ implies finite-$\Sigma^1_1$-$\text{AC}_0$ over RCA$_0 + \Sigma^1_1$.

**Theorem 3.15.** IRT$_{XYZ}^*$ implies ABW$_0$ over RCA$_0$. Therefore IRT$_{XYZ}$ implies ABW$_0$ over RCA$_0 + \Sigma^1_1$.

**Theorem 3.16.** $\Delta^1_1$-$\text{CA}_0 \nvdash$ IRT$_{XYZ}$, IRT$_{XYZ}^*$.

**Theorem 3.17.** ABW$_0 \nvdash$ IRT$_{XYZ}$, IRT$_{XYZ}^*$.

These nonimplication results use previously known models. Goh [ta] proves an additional implication and uses a technically difficult new argument based on a variation of Steel forcing to provide new separations.

**Theorem 3.18** (Goh [ta]). ABW$_0 + \Sigma^1_1$ is strictly stronger than finite-$\Sigma^1_1$-$\text{AC}_0$.

**Theorem 3.19** (Goh [ta]). $\Delta^1_1$-$\text{CA}_0 \nvdash$ finite-$\Sigma^1_1$-$\text{AC}_0$ and so, as $\Delta^1_1$-$\text{CA}_0 \vdash$ weak-$\Sigma^1_1$-$\text{AC}_0$ (Simpson [2009, Ex. VIII.4.14]), finite-$\Sigma^1_1$-$\text{AC}_0$ is strictly stronger than weak-$\Sigma^1_1$-$\text{AC}_0$.

### 4 Almost Theorems of Hyperarithmetic Analysis

Bowler, Carmesin and Pott [2015, top of p. 2] sketch a reduction of IRT$_{UES}$ to IRT$_{UVS}$. While the proof sketch appears to be elementary, a closer look shows that underneath it seems to use principles that are THAs and about as strong as the ones being proven equivalent. Our expectation was that these principles, like the IRT$_{XYS}$, themselves would also prove to be THAs. That turned out not to be the case. Rather, the graph-theoretic principle that they used (about being able to restrict attention to locally finite graphs) implied (over ACA$_0$) some known THA. The unusual aspect of the situation was that we could prove that it was not possible to show that they implied any known THA in RCA$_0$. In particular they did not even imply ACA$_0$. This led to the definition and analysis of ATHAs in Shore [ta] on which we report in this section. For various reasons we do not consider double rays in this section and so use only the subscripts $X$ and $Y$ when appropriate. For these cases, our variants of the principle they use (with UV for XY) are as follows:

**Definition 4.1.** LF$_{XY}$: Every $X$-graph which contains arbitrarily many $Y$-disjoint rays contains a locally finite subgraph which also contains arbitrarily many $Y$-disjoint rays.
The starting point of our analysis is that, for each choice of X and Y, LF\textsubscript{XY} + ACA\textsubscript{0} is equivalent to IRT\textsubscript{XY} over RCA\textsubscript{0} and so is a THA. To see that the LF\textsubscript{XY} are all ATHAs we need to prove that none imply ACA\textsubscript{0}. We actually prove much more.

We also prove by the same methods that many other principles are ATHA. Indeed, we prove not only that they do not imply ACA\textsubscript{0} but that they are very weak over RCA\textsubscript{0}. To be specific, we show that they can each be forced by a notion of forcing from a general class of tree forcings without adding branches to trees lacking them or any (of countably many specified) new sets. Moreover, any such principle is highly conservative over RCA\textsubscript{0}.

**Definition 4.2.** Each of our classes of formulas consists of a base class which includes the quantifier free formulas and is then closed under conjunction (\&, disjunction (\lor), first-order quantification (\forall x and \exists x for number variables) and universal second-order quantification (\forall X for set variables). The G-\Pi\textsubscript{1}\textsuperscript{1} class of formulas has only the quantifier free ones in its base. The G-r-\Pi\textsubscript{1}\textsuperscript{2} class of formulas also has in its base all formulas which are of the form \exists Y\Theta(Y) where \Theta is \Sigma\textsubscript{0}\textsuperscript{3}. The G-Tanaka class of formulas instead adds to the base class all formulas of the form \exists! Y\Phi(Y) for arithmetic \Phi. The G-r-Tanaka class also includes in its base all formulas of the form \exists! Y\exists Z\Psi(x, Y, Z) with \Psi a \Sigma\textsubscript{0}\textsuperscript{3} formula.

For a class \Gamma of formulas, a theory T is \Gamma-conservative over one S if, for every sentence \varphi \in \Gamma, T \vdash \varphi \rightarrow S \vdash \varphi. If S is RCA\textsubscript{0} we omit mentioning it.

We assume a basic familiarity with forcing. This can be carried over to forcing over models of second-order arithmetic satisfying RCA\textsubscript{0} without too much trouble. Our basic class of tree forcings have many familiar examples even with the effectiveness notion we require. The definition of the uniform version is more technical but most of the familiar examples are also uniform or can be made so.

**Definition 4.3.** A notion of forcing \mathcal{P} = \langle P, \leq \rangle is a tree forcing (t-forcing) if the following hold:

1. Conditions in \mathcal{P} are of the form \langle \tau, T \rangle where T \in S(N) is a subtree of N\textsuperscript{<N} (i.e. a subset of N\textsuperscript{<N} in N closed under initial segments with respect to \subseteq) and \tau is comparable with every \sigma \in T. The root of T is taken to be the empty string. The stem of T is defined to be the longest string comparable with every element of T.

2. If \langle \tau', T' \rangle \leq \langle \tau, T \rangle then \tau' \supseteq \tau and T' \subseteq T.

3. For every n \in N the class \{\langle \tau, T \rangle \mid |\tau| \geq n\} is dense in \mathcal{P}, i.e.

   \forall \langle \tau, T \rangle \in \mathcal{P})(\exists \langle \tau', T' \rangle)(\langle \tau', T' \rangle \leq \langle \tau, T \rangle \& |\tau'| \geq n).

**Definition 4.4.** A tree notion of forcing \mathcal{P} is an effective tree forcing (et-forcing) if, for every \langle \tau, T \rangle \in \mathcal{P}, the class Ext(\langle \tau, T \rangle) = \{\tau' | (\exists T')(\langle \tau', T' \rangle \leq \langle \tau, T \rangle)\} is \Sigma\textsubscript{1}\textsuperscript{0}, i.e. there is an A \in S(N) such that Ext(\langle \tau, T \rangle) is \Sigma\textsubscript{1}\textsuperscript{0}(A) (over N).
Definition 4.5. An et-forcing $\mathcal{P}$ is uniform (a uet-forcing) if, for every condition $⟨\tau, T⟩$, every $\rho, \sigma \in Ext(⟨\tau, T⟩)$ with $|\rho| = |\sigma|$, and every $⟨\rho'', R''⟩ ≤ ⟨\rho', R'⟩ ≤ ⟨\tau, T⟩$ with $\rho \subseteq \rho'$, $⟨\rho''_\sigma, R''_\sigma⟩ ≤ ⟨\rho'_\sigma, R'_\sigma⟩ ≤ ⟨\tau, T⟩$. For technical convenience we also require that if $⟨\tau, T⟩ \in \mathcal{P}$ and the stem of $T$ is some $\sigma \supseteq \tau$ then $⟨\rho, T⟩ ≤ ⟨\tau, T⟩$ whenever $\sigma \supseteq \rho \supseteq \tau$. Note: For $\sigma \in T$, $T_\sigma = \{\mu_\sigma|\mu \in T\}$ where $\mu_\sigma(i) = \sigma(i)$ for $i < |\sigma|$ and $\mu_\sigma(i) = \mu(i)$ for $i ≥ |\sigma|$.

Common examples of uet-forcings are Cohen, Mathias and Silver forcings and many variations. The usual versions of Laver and Sacks forcings are et but not uniform. Sacks variation can be applied to Laver forcing. We now want to know that these notions of forcing can be made so by using “uniform” trees as in Lerman [1983, VI.2.3]. A similar variation can be applied to Laver forcing. We now want to know that these notions of forcing have various preservation properties.

Theorem 4.6. If $\mathcal{P}$ is an et-forcing over a countable model $\mathcal{N}$ of RCA$_0$, there is a countable collection $\mathcal{D}$ of dense sets (including the ones specified in Definition 4.3) such that

1. If $G$ is $\mathcal{P}$-generic for $\mathcal{D}$, then $\mathcal{N}[G] \models$ RCA$_0$.
2. If $R$ is a subtree of $\mathcal{N}^{<\mathcal{N}}$ (not necessarily in $S(\mathcal{N})$) with no branch in $S(\mathcal{N})$, then there is a countable collection $\mathcal{D}' \supseteq \mathcal{D}$ of dense sets such that if $G$ is $\mathcal{P}$-generic for $\mathcal{D}'$, then there is no branch of $R$ in $\mathcal{N}[G]$.
3. Thus for any countable collection $R_i$ of trees as in 2 (such as all those in $S(\mathcal{N})$) there is a single $\mathcal{D}'$ as in 2 which works for every $R_i$. In particular, for a set $\{C_i|i \in \omega\}$ with $C_i \subseteq \mathcal{N}$ and $C_i \notin S(\mathcal{N})$ for every $i \in \omega$, there is a $\mathcal{D}' \supseteq \mathcal{D}$ such that, for any $\mathcal{D}'$-generic $G$, no $C_i \in \mathcal{N}[G]$.

It is now easy to see that if, for any theory $T$ and countable model $\mathcal{N}$ of RCA$_0$, we can iterate et-forcings to produce an extension $\mathcal{N}_\infty \models T$, $T \not\models$ ACA$_0$. (Start with the recursive sets as $\mathcal{N}$ and iterate the forcings without adding the set $0'$.). So no such $T$ can be a THA.

We want to prove that we can also use these notions of forcing to derive the $\Gamma$-conservativity of theories $T$ for the classes $\Gamma$ of Definition 4.2. All of our proofs have the same general format. For the sake of a contradiction, we assume that there is a sentence $\Lambda \in \Gamma$ such that $T \models \Lambda$ and a countable model $\mathcal{N} \models \neg\Lambda$ of RCA$_0$. We then construct, by iterated forcing, a model $\mathcal{N}_\infty$ of $T$. If we can also guarantee that $\mathcal{N}_\infty \models \neg\Lambda$, we have proven $\Gamma$-conservativity.

Typical arguments of this sort deal with $T$ whose axioms (other than RCA$_0$) are $\Pi^1_2$ principles, i.e. sentences of the form $\forall X (\Phi(X) \rightarrow \exists Y \Psi(X, Y))$ with $\Phi$ and $\Psi$ arithmetic. One shows that for each such axiom $Q$ and countable model $\mathcal{M}$ of RCA$_0$ and instance of $Q$ given by some $X$ with $\mathcal{M} \models \Phi(X)$, one has a notion of forcing and a collection of dense sets such that, for any generic $G$, $\mathcal{M}[G] \models \exists Y \Psi(X, Y)$. (We say that the forcing adds a solution for the instance of $Q$ given by $X$.) One can then perform an $\omega$ length iteration.
to construct $\mathcal{M}_\infty$ such that each instance of each $Q \in Y$ in $\mathcal{M}_\infty$ gets a witness there as well. As $\mathcal{M}$ and $\mathcal{M}_\infty$ have the same first-order part, it is easy to see that $\mathcal{M}_\infty \models T$ and any $\Pi^1_1$ sentence $\Lambda$ false in $\mathcal{M}$ remains false in $\mathcal{M}_\infty$. The crucial point here is that as $\Phi$ and $\Psi$ are arithmetic, truth and falsity of all instances of $Q$ are preserved upward in the iteration. We prove that the truth of negations of $G$-$\Pi^1_1$ sentences are also preserved by an induction argument. If the forcings needed are uet then we get $G$-$r$-$\Pi^1_2$ conservativity. If the forcings are uet, we get $G$-Tanaka and $G$-$r$-Tanaka conservativity. These results strengthen many known conservation theorems.

In terms of ATHAs and various stronger principles, however, we are interested in situations where the axioms of $T$ are more complicated. Our starting examples are the $\text{LF}_{XY}$ (Definition 4.1). Here the axioms/principles $Q$ are as above but $\Phi$ and $\Psi$ are of the form $\forall n \exists Z \Theta$ with $\Theta$ arithmetic (saying $Z$ is a sequence of disjoint rays of length $n$). We prove that for any graph which is an instance of an $\text{LF}_{XY}$ there is an et (indeed uet) forcing that adds a solution, i.e. a locally finite subgraph with the desired sequences of disjoint rays. While the added solutions remain solutions in $\mathcal{N}_\infty$, we may have new instances that did not seem to be instances at any point along the way: The required witnesses $Z$ for some $X$ may appear cofinally in the iteration. So $\mathcal{N}_\infty$ may not be a model of $\text{LF}_{XY}$. The natural plan here is to continue the iteration to length $\omega_1$ as any assumed witnesses for an $X$ appearing in $\mathcal{N}_\infty$ must then also appear at some stage of the length $\omega_1$ iteration and so have a solution added at some point as well.

**Theorem 4.7.** For each of the $\text{LF}_{XY}$ there are uet-forcings that add solutions for any instance. Thus all of them together are $G$-$r$-Tanaka (and so $G$-Tanaka, $G$-$r$-$\Pi^1_2$ and $G$-$\Pi^1_1$) conservative over $\text{RCA}_0$. As over $\text{ACA}_0$ each implies $\text{IRT}_{XY}$ which is a THA, each of them is an ATHA.

The $\text{SCR}_{XY}$ are equivalents of the corresponding $\text{IRT}_{XY}$. We can adjust them slightly to get other ATHAs which are equivalent to $\text{IRT}_{XY}$ only over $\text{ACA}_0$. One example is that we just require that the sequence $\langle R^n \rangle$ has each $R^n$ being a sequence of almost (i.e. up to finite difference) disjoint rays of length $n$. We also consider variations of an array of known strong principles that provide versions that are $\Gamma$-conservative for all the class of Definition 4.2 but very strong over $\text{ACA}_0$.

**Definition 4.8.** $\Sigma^1_{n+1}$-$\text{AC}^*$: $\forall A[\forall n \exists X \Phi(A, n, X) \rightarrow \exists Y \forall n \exists \sigma \Phi(A, n, Y^{[n]}_\sigma)]$, for $\Phi \Pi^1_n$.

(Note: For $Y \in N^N$ and $\sigma \in N^{<N}$, we define $Y_\sigma$ by $Y_\sigma(i) = \sigma(i)$ for $i < |\sigma|$ and $Y_\sigma(i) = Y(i)$ for $i \geq |\sigma|$.)

$\Sigma^1_{n+1}$-$\text{AC}^-$: $\forall A[\forall n \exists X \Phi(A, n, X) \rightarrow \exists Y \forall n \exists m \Phi(A, n, Y^{[m]}_\sigma)]$ for $\Phi \Pi^1_n$.

$\Sigma^1_{\infty}$-$\text{AC}^*$ and $\Sigma^1_{\infty}$-$\text{AC}^-$ assert, respectively, that $\Sigma^1_n$-$\text{AC}^*$ and $\Sigma^1_n$-$\text{AC}^-$ hold for all $n \in \omega$.

**Theorem 4.9.** For each $n \in \omega$, $\text{RCA}_0 \vdash \Sigma^1_{n+1}$-$\text{AC} \rightarrow \Sigma^1_{n+1}$-$\text{AC}^* \rightarrow \Sigma^1_{n+1}$-$\text{AC}^{-}$ and $\text{ACA}_0 \vdash \Sigma^1_{n+1}$-$\text{AC}^{-} \rightarrow \Sigma^1_{n+1}$-$\text{CA}$. So over $\text{ACA}_0$, all of $\Sigma^1_{\infty}$-$\text{AC}^*$, $\Sigma^1_{\infty}$-$\text{AC}^-$ and $\Sigma^1_{\infty}$-$\text{CA}$ are equivalent as are $\Sigma^1_{n+1}$-$\text{AC}$, $\Sigma^1_{n+1}$-$\text{AC}^*$ and $\Sigma^1_{n+1}$-$\text{AC}^{-}$ for each $n$.

**Theorem 4.10.** $\Sigma^1_{\infty}$-$\text{AC}^*_0$ is $\Gamma$-conservative for all the classes $\Gamma$ of Definition 4.2 and so are all the $\Sigma^1_{n+1}$-$\text{AC}^*_0$ and $\Sigma^1_{n+1}$-$\text{AC}^-_0$ by the previous theorem.
So, in particular, $\Sigma^1_1\text{-AC}_0^*$, $\Sigma^1_1\text{-AC}_0^-$, $\Sigma^1_\infty\text{-AC}_0^*$ and $\Sigma^1_\infty\text{-AC}_0^-$ are highly conservative over RCA$_0$ but over ACA$_0$ each of the first pair are equivalent to $\Sigma^1_1\text{-AC}_0$ (and so are ATHAs) and each of the second pair are equivalent to $\Sigma^1_\infty\text{-AC}_0$ and so stronger than full second-order arithmetic. (See Simpson [2009, Remark VII.6.3].) Some earlier conservation results for some of the theories covered here are in Yamazaki [2000], Kihara [2008] and in Yokoyama [2009] as well as in work of Tanaka, Montalbán and Yamazaki as reported in Yamazaki [2009].

The proof of Theorem 4.9 is combinatorial and proceeds by induction on $n$. Theorem 4.10 is proven by providing et- or even uet-forcings that add solutions for $\Sigma^1_\infty\text{-AC}_0^*$. Now $\Sigma^1_\infty\text{-AC}_0^*$ has both hypotheses/instances $\Phi(X)$ and conclusions/solutions $\Psi(X,Y)$ of arbitrary complexity. Thus we need another idea to guarantee that adding what looks like a solution stays a solution in $\mathcal{N}_\infty$ as well as a procedure that makes sure we handle everything that is an instance in $\mathcal{N}_\infty$ along the way. The crucial idea here is to use the fact that if we do an $\omega_1$ iteration to produce models $\mathcal{N}_\alpha$ for $\alpha < \omega_1$ then, for a closed unbounded set of $\lambda < \omega_1$, $\mathcal{N}_\lambda$ will be an elementary submodel of $\mathcal{N}_\infty$. Thus, if we carefully handle everything that looks like an instance in such an $\mathcal{N}_\lambda$ and supply something that looks like a solution, all will be well at the end.

We view these results and the previous ones on ATHAs that are equivalent to known THAs over ACA$_0$ as supplying answers to the question raised by Hirschfeldt and repeated in Montalbán [2011] by providing an ample list of many pairs of principles that are very different over RCA$_0$ but equivalent over ACA$_0$. It could well be argued that these weak ones should really be seen as the same as their strong counterparts in an analysis that works over ACA$_0$ rather than RCA$_0$.
